policy during the last five years. They have had two objects: the first, to attract to the schools the services of one or two young dental practitioners of high standing, to devote whole or part time to operative dental surgery, orthodontics, or allied clinical subjects; and the second, to encourage the schools to set up better-paid posts of professorial rank. The scheme of bursaries for dental education was adopted in 1923, and up to the end of last year 702 bursaries had been awarded, and 355 of the bursars to whom grants were made had qualified. The grants made by the Dental Board to research have had a 'two-fold channel'—namely, through the Department of Scientific and Industrial Research and through the Medical Research Council. By means of a Dental Investigation Committee of the Department profitable researches have been carried out on dental models and materials. Recent fluctuations in the Board's income, owing to the lowering of the retention fee—a concession to hard-hit dentists—has compelled the Board to withdraw support from these researches. Lord Rutherford, the chairman of the General Board of the Department, in a letter acknowledging the generosity of the Dental Board over many years in financing this work, expresses the hope that the Board may see its way at a future date to make renewed provision for a programme of investigation, and with that in view the results so far reached are to be placed on record as a starting-point for further work. On the medical side several researches are in progress under the auspices of a committee of the Medical Research Council for the investigation of dental disease. The most important is that on diet and the teeth, by Dr. May Mellanby, who has shown that teeth of good structure can be produced in certain animals by a dietary having a low cereal content but rich in vitamin D. Sir Francis Acland, in commenting, as a layman, on Mrs. Mellanby's work, suggested that it would be useful to have, alongside her conclusions establishing the importance of diet in dental structure, some more complete experiments than had yet been possible upon the effect of perfect environment, apart from attention to diet. Finally, with regard to the Board's work for dental education, the chairman said that this was winning appreciation from health and education authorities. In the jargon of the day, it is making the younger generation "tooth-minded." A cynic might say that the Board by its benefactions is doing its best to ensure that the dental profession of the future shall be highly educated but without any patients. A truer view would be that the work of the dentist will become increasingly preventive.

VACCINE THERAPY IN BACTERIAL ENDOCARDITIS

Dr. C. Dimitracoff has lately reported the results of treatment with autogenous vaccines in four patients with subacute bacterial endocarditis. The vaccine was made in all cases from a streptococcus grown from the blood. The organism was of the *viridans* type in three instances, and all these patients were cured. In the fourth a streptococcus of haemolytic type was obtained, and this patient died in spite of vaccine therapy. As other authors have reported failure with this, as with all other methods of treatment, the

criteria of diagnosis must be completely satisfied if we are to accept these reports of success. In the author's first case it must be objected that there was no evidence of valve disease, and the presence of heart failure is also an argument against the diagnosis. This last objection applies also to the third case, yet in this instance the existence of valvular disease, a large spleen, and positive blood culture provide the strongest evidence for the diagnosis. There were no emboli in either Case 1 or Case 3, and clubbing of the fingers is not mentioned. No details are given of Case 2; finally in Case 4, with clear evidence of valve disease, and multiple emboli, there can be no doubt as to the presence of infective endocarditis, but for this patient treatment was unsuccessful.

SANATORIUM EXPERIENCE

The twenty-seventh report of King Edward VII Sanatorium, Midhurst, covers the twelve months ending June, 1933, during which 320 patients were admitted and 220 discharged. Artificial pneumothorax was employed in 173 cases, and it is hoped to publish a special report soon to amplify that which appeared in the *Quarterly Journal of Medicine* for July, 1932. The number of operations for phrenic evulsion (66) and thoracoplasty is thought to warrant special notice, and detailed accounts of these will be published later. The first-named procedure has produced interesting results in cases of apical disease. Thirteen patients have been submitted to thoracoplasty in the last five years; twelve are still alive, with an after-history of six months to five years, and eight of these have now a tubercle-free sputum. It is noteworthy that two of these eight had originally laryngeal tuberculosis, which did not improve under treatment by rest, but which healed shortly after the operation. Six of the twelve patients are now at work. The after-history of seventy-seven patients who had gold treatment has now been followed up. Eleven have died. In four cases an artificial pneumothorax operation was associated with the gold treatment, and one had phrenic evulsion performed. Of the sixty-six surviving patients thirty-nine have now no sputum, or tubercle bacilli are not present in it; twenty-seven cases are still positive, three of these having had also artificial pneumothorax, and one a thoracoplasty. The pathological department finds no support for the impression that the reading of the sedimentation test, when performed a second time—after one month's residence in the sanatorium—is more often higher than lower. No change occurred in the rate in 6.2 per cent. of the cases; in the remainder it was as often lowered as raised. An attempt was made to test comparatively the accuracy of the micro method of performing this test. The conclusion was reached that for practical clinical purposes the micro method was quite accurate enough, especially when repeated frequently, as it should be. Marked errors usually occurred only in abnormal rates. Intense auto-agglutination giving a false normal reading could always be identified by close inspection of the column of blood. Radiographical reproductions are included in the report to illustrate the difficulty of diagnosis of a cavity. Clinically, in a certain case there was some whispering pectoriloquy in the right upper zone in front, but this was not sufficiently defined to warrant

a positive diagnosis. The first film taken suggested the presence of excavation, but was not conclusive. After semi-collapse of the lung by artificial pneumothorax, a second film proved the presence of a large cavity. A new departure at Midhurst has been the provision of an operating theatre, so that all surgical procedures now employed in the treatment of pulmonary tuberculosis can be undertaken in the sanatorium.

OVULATION IN THE WOMAN

Until quite recent years the current view was that menstruation in the woman corresponded with pre-oestrus in the bitch. The brilliant results obtained by direct experiment on animals, particularly by the American school, have led to a complete reorientation of our ideas. It is now accepted that ovulation and pregnancy can occur without menstruation and menstruation without ovulation. There are some who would insist that anovular menstruation should not be called "menstruation," but seeing that the term was introduced centuries before its association with ovulation was understood, and that even now the diagnosis between ovular and anovular menstruation can only be determined by the histological examination of material removed by the curette, this point of view is perhaps unnecessarily precise. It is generally agreed that ovulation takes place normally between the tenth and the fourteenth day of the menstrual cycle, and that the rate of degeneration of the ovum is such that it becomes incapable of being fertilized within seven days of being extruded from the ovary. It follows that there are only about six days in the menstrual cycle when the ovum can be fertilized. Recent work has suggested that the spermatozoon does not live longer than about forty-eight hours in the female genital tract, and some authors have stated with assurance that a woman whose periods are absolutely normal can become pregnant only if coitus occurs between the eighth and seventeenth days of the menstrual cycle. If this were so, the problem of birth control would be relatively simple of solution. While it is true that conception is most likely to take place at this time, there would appear to be unequivocal clinical evidence that it may follow coitus on any day of the cycle. It must be concluded either that ovulation does not always happen between the tenth and fourteenth days of the cycle, or that the spermatozoa can live, as was formerly believed, for as long as three weeks in the female genital tract. It is, of course, possible that ovulation may happen more than once during each menstrual cycle. Investigating this question, Séguy and Simonnet¹ have sought to correlate with ovulation the appearance of a thin glairy fluid in the cervical canal (which persists for three to four days) and the maximum concentration of folliculin in the urine. They believe the glairy fluid to be secreted for the purpose of rendering the cervical canal permeable to the spermatozoa. Artificial insemination proved successful in two patients, the operation being performed when the secretion was at its height. The same operation was unsuccessful in a third patient, although performed at the same phase of the cycle in three consecutive months. A study of the urinary folliculin showed that it did not reach its highest concentration

¹ *Gynéc. et Obstét.*, 1933, xxvii, 657.

until the twenty-second and twenty-third days of the cycle. At this time there was a second and sub-maximal secretion of the glairy cervical fluid. Artificial insemination at the twenty-first day of the cycle subsequently proved successful. If this work is confirmed, it would seem that the coexistence of the glairy cervical discharge with the maximum amount of folliculin in the urine indicates the time of ovulation—a point of value in the treatment of sterility.

ANTIMONY POISONING FROM ENAMELLED VESSELS

A report by Dr. G. W. Monier-Williams on "Antimony in Enamelled Hollow-ware" has been issued by the Ministry of Health.¹ It shows that an unexpected and hitherto scarcely realized risk lurks in the use of certain hollow-ware receptacles for the preparation of lemonade. Several specific outbreaks of antimony poisoning during the last few years have been traced to such receptacles, and they are due to the tartaric acid in the "lemonade crystals" or the citric acid in lemon juice dissolving some of the antimony oxide used in the manufacture of the white enamel coating. For instance, the 120 people present at a social gathering were served with lemonade, made of sliced lemons, which had been prepared in large white enamel jugs, and in half an hour thirty persons were sick. An analysis of the lemonade showed the presence of antimony, whilst the enamel of the jugs was found to contain 9 per cent. of antimony oxide. In another instance the sickness was so severe that some of the patients had to be removed to hospital, but they recovered by the next day. The antimony oxide is employed as a cheap substitute for the more usual tin oxide, which is non-poisonous, and it does no harm when used for articles such as baths, sinks, and clothes-boilers, which are never likely to come into contact with liquid or solid foods. The report suggests that the total prohibition of antimony in any hollow-ware articles capable of being used as receptacles for food might be best for the interests both of the public and of the trade. The increase in the cost of production would be only 3 or 4 per cent., and it appears that the trade would not object provided that the restriction applied equally to imported goods.

THE NOGUCHI LECTURES

Nothing perhaps would have puzzled Noguchi more in his puzzled life than the Hideyo Noguchi lectures of 1933, which are now issued as vol. 1 of the third series of the publications of the Institute of the History of Medicine of the Johns Hopkins University.² Noguchi was a brilliant and simple-minded bacteriologist coming from the lowest class in Japan. He lived for and in his laboratory, where he daily performed the juggling feat of eating rice with chopsticks in one hand whilst he held a book in the other. He died of yellow fever at Accra on the Gold Coast on May 21st, 1928. Nevertheless Dr. Castiglioni, who is professor of the history of medicine at the University of Padua as well

as the chief medical officer to the Austrian Lloyds at Trieste, has done good service by these lectures on the renaissance of medicine in Italy. The first deals with the dawn of the Renaissance and centres round Leonardo da Vinci and Vesalius; the second with the flowering of the Renaissance, which is dominated by Berengario da Carpi and Caesalpinus; the third with the legacy of the scientific renaissance and the main currents of thought from Fracastoro to Galileo. Each lecture is full of thought and all are well worth reading. Speaking of the rise of anatomy he says Vesalius gave the impress of his own personality; Leonardo is a solitary thinker who despises previous tenets. Vesalius feels the link between himself and his forerunners, between himself and his followers. He realizes his debt to the first and is conscious of his power over the second. His work is conceived and complete in the smallest details, and this explains his marvellous success. The lectures are introduced by a preface from the pen of Professor Sigerist, and there is a portrait of Dr. Castiglioni which does not wear the happy expression we are accustomed to associate with his joyous personality.

VITAMIN STANDARDIZATION

An international conference on vitamin standardization is being held this week at the London School of Hygiene and Tropical Medicine, under the auspices of the Permanent Commission on Biological Standardization of the Health Organization of the League of Nations. This conference is the second of its kind. The first, held in 1931, established standards and units for vitamins A, B₁, C, and D, which have since been widely used in many countries throughout the world. Although the standards originally recommended have on the whole worked well, the rapid advance of scientific work in this field has made it necessary to review the findings of the first conference in the light of recently acquired knowledge. Several vitamins are now available in a relatively pure state, and it is probable that the present conference will recommend the replacement of the standards chosen in 1931 by purer preparations than were available at that date, especially in the case of vitamins C and D. The chairman of the conference is Professor Edward Mellanby, and the technical secretaries are Dr. W. R. Aykroyd (League of Nations, Geneva) and Dr. Harjette Chick (Lister Institute, London).

The May meeting of the Joint Tuberculosis Council was largely devoted to a discussion of human tuberculosis of bovine origin and the examination of contacts. A committee was appointed, consisting of Professor W. W. Jameson (convener), with Drs. Jas. Watt, C. O. Hawthorne, W. H. Tytler, Lissant Cox, Jane Walker, Esther Carling, Neville Cox, and D. P. Sutherland, "to study and report upon the milk supply in reference to the promotion of health and the prevention of disease, especially tuberculosis." Concerning the routine examination of contacts, doubt was expressed as to the value of the methods usually adopted, and finally a second committee was formed, consisting of Dr. Ernest Ward (convener), with Drs. F. W. Goodbody, D. P. Sutherland, J. C. Gilchrist, G. T. Hebert, G. Jessel, W. Burton Wood, and L. S. T. Burrell, "to consider and report upon the examination of contacts and the discovery of early or latent tuberculosis, especially among adolescents."

"EXPERIMENTS ON MAN"

PROFESSOR BARCROFT'S STEPHEN PAGET MEMORIAL LECTURE

The eighth Stephen Paget Memorial Lecture, which was part of the annual general meeting of the Research Defence Society, was delivered by Professor Joseph Barcroft, F.R.S., of Cambridge, in the hall of the London School of Hygiene and Tropical Medicine, on June 5th. Lord Lamington presided over a large audience, which included a few anti-vivisectionists.

Professor Barcroft limited himself to researches which were upon human beings, but were such that they would have to be conducted under the Act of 1876 were man regarded as a "vertebrate" in the sense of that Act. As to whether the results of experiments performed on animals could be regarded as applicable to man, he said that the question was one which could not be answered "yea" or "nay" without an implication which would be untrue. The results of such experiments as could be performed on animals could as a rule be transferred to man, though not without some reservations, which varied with the nature of the experiment.

OBJECTIVE EXPERIMENT

The lecturer first considered objective experiments—for example, the administration of simple chemical substances, which in one way or other acted on the relatively uncomplicated processes of living protoplasm. The mode of action of hydrocyanic acid was now known; it prevented the oxidation processes of the body by destroying the action of the enzymes concerned. There was no reason to suppose that these essential processes of life in man differed materially from those in other mammals; weight for weight the lethal dose of prussic acid was likely to be of the same order throughout the warm-blooded animals. Here he exhibited a number of curves showing the strength of prussic acid vapour in air which proved fatal to various mammals in the time given. It was likely that somewhere within these limits, or not far outside them, the curve for man would fall. If it was desired to know how long a man could survive a concentration of 0.6 mg. of hydrocyanic acid gas per litre the answer would be that he was exceedingly unlikely to die if exposed for less than one minute, and extremely unlikely to live if exposed for much more than fifteen minutes. This was known to be correct so far as the inferior limit was concerned, because the matter had been put to the test, a man remaining in the gas for upwards of two minutes, and continuing in possession of his faculties. If only it was known why the dog and mouse were so susceptible and the monkey and guinea-pig so resistant, the toxicity of the gas for man could be placed within much narrower limits. The susceptibility of the dog appeared connected with the fact that the dog was capable of a much greater and more sustained degree of activity than most other animals. It could run down almost anything, including man, from which it was to be inferred that the maximal total ventilation of which the dog was capable was for its size greater than for man. The reason why it yielded so quickly to an atmosphere of prussic acid was explained by its power of respiration, whereby it took a much larger quantity of the fatal gas. It was therefore to be predicted that the gas would be much less powerful in its effect on man than on dog. In the experiment just mentioned there was a dog in the lethal chamber with the man, and at the termination of the experiment the dog was moribund.

EXPERIMENT ON SENSATION AND MENTAL PERFORMANCE

The extent to which experiments on animals could yield correct information with regard to human sensation was influenced by the fact that various sensations were developed in very different degrees throughout the

mammals. Some sensations, notably smell, were ill-developed in man as compared with many animals. On the other hand, what might be called the sense of pungency was comparatively highly developed in man: constituents in the air which were intensely irritating to man appeared to have little or no effect on animals. Again, there was the difficulty that even the most experienced experts could not define exactly what was being felt by the animal. So far as experiments on sensation were concerned, the classical one was that of Head and Rivers, who explored the sensations contingent on the cutting, and regeneration, of the nerve going to an area of skin on the forearm. The tragedy of it was that no subsequent observer had found it possible in portraying his sensations to reproduce the picture given by Head and Rivers of epicritic and protopathic sensibility. Three very serious researches had been carried out on this subject from different angles—by the surgeons in the persons of Trotter and Davies, by the psychologist in the person of Boring, and by the physiologist in that of Sir Edward Sharpey-Schäfer. There was unanimity among the observers on two points—that a single experiment would not suffice to teach them correctly to describe their sensations, and that the description in no case supported the theory that crude and delicate sensations differed not only in degree but in kind. The theory of protopathic and epicritic sensation seemed to have gone, but there remained the heroism and example of its originators, and if they did not reach finality it might at least be said that they had laboured and others had entered into their labours.

When the issue was the testing of this or that procedure on the higher mental faculties it went without saying that the subject tested must be man himself. The minimum atmospheric pressure at which differential equations could be solved was not to be decided of a mouse. More than twelve years ago he himself essayed to discover whether the mental abilities of a party of researchers who went with him to Peru were of their usually high standard when living at an altitude of 15,000 ft. in the Andes. The results of suitable mental tests when tabulated showed little or no falling off as compared with those yielded by the same persons at sea-level. Yet the results of the tests were in a sense illusory, for while the work was as well done on the Andes as on the sea, the effort of doing it and the concentration required were enormously greater. Psychological technique since then had made great strides, but the difficulty of expressing in units which could be tabulated the amount which a given performance "took out" of the performer was still a very real one. He was told on high authority that an official of a copper corporation in Peru could write a difficult report as cleverly at Cerro de Pasco as in New York, but in New York he would do it in his stride, while at Cerro he would have afterwards to make a trip down the coast to recuperate.

COMMUNICABLE DISEASE

Finally the lecturer turned to the subject of disease, which in its simplest form might be no more than an upset of the balance of normal conditions in the body. A case in point was the effects of hæmorrhage. The hydrostatic arrangements in the human body were of the same general scheme as in the higher animals, so that the effects of deprivation of blood could be studied quite well on animals, and all the relevant information obtained. It was true that it was an experiment on man which had given him a very broad hint that the volume of circulating blood could be adjusted within limits by the contraction of the spleen; but the proof came entirely from animals, more especially a very striking demonstration that quite a large volume of blood might be lost without prejudice to the actual amount of fluid in circulation. Not only could the effect of diminished blood volume be ascertained by animal experiments, but a great deal of information about possible causes. The production of histamine in wounded tissue, its effects upon the permeability of the vessel walls, and so forth, had all been discovered and demonstrated on

animals. But there were other and more complicated problems connected with the investigation of disease. In communicable diseases there were two problems: first, the organism or virus which was the essential cause, and, secondly, the intermediate host, if any, by which it was communicated. If the disease was one to which a great many forms of life were susceptible, the ground might be cleared by experiments upon animals. Such was the case with plague, the typical symptoms of which were shown by mice; rats, guinea-pigs, and rabbits when inoculated, while rats, mice, and monkeys, when fed on cultures of plague bacilli, acquired the disease and generally died with characteristic symptoms and lesions. When, however, the disease was one which was not known to reproduce its symptoms in any form of animal life, the human experiment was imperative. The history of trench fever was a case in point. In yellow fever, again, when the subject became ripe for experimental work, there was believed to be no experimental animal which could be used, for the simple reason that no animal was known to be capable of taking yellow fever. It was possible, however, since there were numerous strains of yellow fever, to take advantage of human volunteers in working up from the harmless to the harmful.

To sum up, purely objective experiments did not, as a rule, demand the use of man; in a great many cases the relevant information could be obtained on animals. Experiments on sensation and on mental perception must usually be carried out on man himself. As regards the communication of disease, if animals showed the symptoms of the malady they could be used for clearing the ground; if they did not, resort must be had to human experiment. The proof that plague could be communicated to man was first supplied by a worker who injected himself with blood from a plague patient. If to-day the matter could be settled with a high degree of certainty on rats and monkeys, would not such act, though one of heroism, verge on unjustifiable suicide? Condemned criminals had been mentioned as possible subjects for experiment, but Professor Barcroft, owing principally to the obvious abuses to which such a course was open, not to speak of the paucity of condemned criminals, was against such forms of experiment. The Research Defence Society, he said in conclusion, was pledged to animal experimentation, because it was thought that many of the problems could be solved most readily and humanely by that method, but any other method which would be of use was welcomed none the less. With the policy of waiting for the illuminating accident, of folding the cards and wrapping the talent in the napkin, they would be nothing to do.

A vote of thanks was accorded to Professor Barcroft for the motion of the Hon. Sir Arthur Stanley, seconded by Professor A. V. Hill. The latter mentioned that Professor Barcroft's experiments had been done largely on himself. Outside the hall leaflets were distributed charging Professor Barcroft with doing certain mutilating experiments, and he was asked by a member of the audience whether he admitted the charge. He replied that while the individual statements, or some of them, the leaflet might be correct, the general implication that he tortured animals was quite untrue. Not long ago an anti-vivisectionist asked permission to inspect his animal houses. He replied that permission could be given to inspect the animals except those which had actually been under experiment. The anti-vivisectionist accepted the limitation, made his inspection, and professed himself very pleased with the condition of all the animals he saw. But in fact, unknown to the visitor, all the animals which had actually undergone experiment were included among those he inspected!

The issue of *La Medicina Ibera* for May 17th contains an illustrated description of the Spanish Health Congress which was recently held at Madrid. There was an attendance of 1,400, and 280 papers were presented. The next congress will be held in 1937 at a place to be arranged by the executive committee.

KING EDWARD'S HOSPITAL FUND

The annual meeting of the General Council of King Edward's Hospital Fund for London was held on June 5th. The Prince of Wales presided, and read a message from the King expressing his satisfaction at the news that the hospitals appeared to have fared even better in 1933 than in 1932.

PRESIDENT'S ADDRESS

The Prince announced that the Fund had again maintained its ordinary distribution at £300,000 entirely out of annual income. Another £8,000 had been issued in pension scheme grants, together with £12,000 from the special pensions reserve, the total of the two distributions amounting thus to £320,000. The net income of the year, £308,000, was an increase of £5,000 over that of 1932. Legacies, which for six years past had never provided less than £58,000 annually, and had averaged £68,000, totalled £80,000 in 1933. There were some decreases in annual subscriptions (£2,000) and in income from investments (£11,000), but the Fund's capital had been increased by the reversion of £136,000 under the will of Lord Mount Stephen, and a gift of freehold property valued at £18,000, to be called the William and Francis Radford Endowment. The Prince called attention to the great amount of administrative work involved in distributing the annual £300,000. This required a whole twelve months' examination of the affairs of the hospitals by the Distribution Committee, the Hospitals Economy Committee, the Revenue Committee, and the Visitors. The Fund had also come to exercise some of the functions of a kind of central body for the voluntary hospitals of London, using its influence while carefully respecting their individuality and freedom. No fewer than eight separate subjects had been taken up by the Fund last year, as the result of communications from responsible correspondents who had wished to approach the hospitals through a central agency. Staff help had also been given to the London Voluntary Hospitals Committee, the representative body which consulted with the London County Council about the provision of hospital accommodation in the county. The Parliamentary Committee was actively concerned with the problem of payment for the treatment of motor accident casualties, and was reviewing the question of private Bills promoted by individual hospitals which could not otherwise provide pay-beds for patients of moderate means, and the advantages to be derived from a general Bill which would deal with them all. The Out-patient Arrangements Committee was issuing a second edition of its hospital out-patient time table, designed to ensure that patients need not have to wait through having come at the wrong hour. It had also presented a report on the ways in which the District Nursing Service could be used to relieve out-patient departments, and was at present studying time-saving methods at the dispensary stage of out-patient procedure. Here again members of the Committee were visiting hospitals to study the procedure directly.

STRENGTH OF THE VOLUNTARY SYSTEM

Although the exact figures for 1933 were not yet available (His Royal Highness continued) it was already clear that the voluntary hospitals had had an aggregate balance of income over expenditure for the seventh year in succession, and that the last year's balance would prove to be the largest of the series. There were fewer hospitals with deficits for the year, and more with surpluses, than at any time since the war. There had been a considerable increase in income, which was now about £4,000,000 in London alone. This was partly due to exceptionally large legacies, but other voluntary income was keeping very steady. Out of the £4,000,000 about £1,800,000 came from voluntary sources, made up of large and small sums, and not including gifts for building or endowment. In addition to this steadiness of voluntary income, the payments of patients had increased, and large amounts were being raised for building schemes. The broad fact was that, during the past few years, between two and three million pounds a year in London alone had come from that stream of voluntary gifts which had so often been said to be drying up—a kind of drying up which would excite the envy of the Metropolitan Water Board. The

hospital service in this country had the advantage of being partly voluntary and partly centralized under the county authorities. There was thus provided a unique opportunity of combining large-scale efficiency with the qualities which came from individual freedom and initiative and were especially important in medical work.

VARIOUS REPORTS

Mr. E. R. Peacock, honorary treasurer of the Fund, moving the adoption of the accounts, said that the increased income had enabled the Fund to provide £5,000 more than in the previous year for pension grants, and also to meet the cost of removal to new and larger offices, which were not out of proportion to the continual increase in the work. The balance sheet had now a separate schedule for the gifts for special purposes, the increase in the number of which was a welcome mark of the confidence in the Fund felt by donors. The Chairman of the Management Committee (the Earl of Donoughmore) reported on an application from the Central Council for District Nursing in London, together with a report by the Out-Patient Arrangements Committee, on the work done by district nurses, in relief of out-patient departments. He moved that the question of a grant should be referred back to the Management Committee for their consideration and for further report to the General Council, and that in the meantime the report be published. Sir William Collins, chairman of the Central Council for District Nursing, acknowledged gratefully the praises for the work of the district nursing service which had been forthcoming from the Prince and from the Out-Patient Committee. He hoped that some grant might now perhaps be received.

Reports of Societies

OTO-LARYNGOLOGICAL MEETING AT BIRMINGHAM

At a summer meeting of the Sections of Otolaryngology and Laryngology of the Royal Society of Medicine at Birmingham University on June 8th and 9th, the chair of the Otolaryngological Section was taken by Mr. W. J. HARRISON, and a discussion on the subject of nerve anastomosis was opened by Sir CHARLES BALLANCE.

Nerve Anastomosis

He said that since 1895 surgeons had been uniting the peripheral end of a divided nerve of the neck to the central end of some other divided nerve. Though after such operation the recovery of the muscles of the face was remarkably satisfactory when compared with the preceding paralysed condition, it was not a perfect recovery. He therefore determined to investigate, by experimental means, as to the best means of operating for facial palsy. Thirty experiments were carried out, and at the end of six months thereafter the voluntary movement and the faradic response were, in several of the animals, normal, the muscles on both sides of the face contracting simultaneously. But when the facial nerve was grafted to the hypoglossal, the descending hypoglossi, or the glosso-pharyngeal nerve, associated movements, varying from slight closure of the eyelids to contractions involving other muscles of the face and pinna, were present. Four years ago he accepted the invitation of Dr. Arthur Duell of New York to work with him on the subject in the surgery of the latter. After nearly a year of experimentation the idea of employing a nerve graft in the Fallopian canal was evolved. Monkeys were the experimental animals. Sir Charles declared that there was no such thing as anastomosis of nerves. The distal segment of a nerve degenerated, and at the end of fourteen days it could be said to be a bundle of tubes containing the broken-down fatty elements of the nerve sheath. In man, the radical mastoid operation should be done before commencing to remove the outer wall of the aqueduct. Obviously, decompression was the course to adopt. The best means of determining whether the operation had been followed by harmonious functioning of the two sides of the face was by the expressions

of emotion. For the use of degenerated grafts instead of fresh grafts Dr. Duell was answerable. The degenerated grafts consisted of a series of tubes filled with fatty masses due to the breaking up of the sheaths. The use of this graft might determine the return of faradic excitability in the muscles of the palsied face in as short a time as a month. In thirteen of the series of twenty-two experiments on baboons spontaneous contractions of the face muscles were observed, and in eight of the thirteen the facial nerve had been grafted to another nerve of the neck. In the remaining five nerve grafting was done. After operations for facial paralysis in humans spasm of muscles was not noted, but it was in the case of monkeys.

Sir HAROLD GILLIES described by means of a cinematographic film his experiences with the fascia lata graft, which was attached to temporal muscle flap. Though it was essentially a palliative procedure, its use had been established, and in cases which seemed likely to recover it constituted a great aid to such recovery. The graft could be taken by either of two methods: by the open, necessitating a long incision in the thigh; or by the closed—that is, making a nick, and inserting a ring cutter inside. The most frequent sites for placing these fascia lata strips were the centre of the lower lip, the centre of the upper lip, and the angle of the mouth. For paralysed eyelids he used the temporal muscle slip plus its own temporal muscle fascia.

Many members discussed these contributions.

Phonation and Articulation

Considerable time was devoted to the question of phonation and articulation. Normal phonation was dealt with by Mr. STEPHEN JONES, who supported his paper by a number of diagrams. Mr. V. E. NEGUS also spoke on disorders of phonation, emphasizing the importance of the thyro-arytenoid muscles in talking and singing, and their function in imparting elasticity to the margins of the glottis. The vocal cords, he submitted, were not necessary for phonation. Miss FRED A. PARSONS, who is in charge of the phonetics clinic at Queen's Hospital, described her method of re-education of the faculty of speech after various operations on the mouth and throat, and demonstrated successful results in several children and in a woman 56 years of age. Part of this success was attributable to the ingenuity with which she managed to maintain the lively interest of her pupils, every few days seeing some new device for them to practise. Mr. BRAYSHAW GILHESPY pointed out that the pitch of consonants was mostly in the region of 8,192 double vibrations per second (tuning fork C₄), the vowel sounds being caused by a much lower rate—that is, 400 to 2,000. If hearing for notes below 2,000 double vibrations per second was lost, the patient was confused in his effort to distinguish certain sounds of vowels. People with nerve deafness failed in reference to their consonants.

Other Papers

Dr. T. C. GRAVES (Birmingham) read a paper on "Sphenoidal Sinus Infection in Relation to Mental Disorder," especially in reference to two female patients, both of whom had to be certified. In both, the mania was found to be due to the existence of closed sinus foci of infection, which brought many ills in its train. In both, treatment of these foci resulted in the ultimate discharge of the patients—one, aged 25, in seven months, the other, aged 41, in three years eight months. Dr. Graves explained that these cases were reported in continuation of the work being done at the mental hospital on these lines.

Mr. MUSGRAVE WOODMAN (President, Section of Laryngology) read a communication on "The Control of Air Pressure in the Lungs after Tracheotomy." The paper was based on a case of chronic obstruction of the larynx. After tracheotomy a wide-bore tube was tied in, and relief was instantaneous, but the patient's happiness lasted only a few hours, for at the end of that time he began to get waterlogged—he had cough, and mucus and saliva streamed out of the tracheotomy opening; he developed oedema of the lungs, became collapsed, and died, not of pneumonia, but of lung collapse. Mr. Negus had

shown that the primary function of the larynx was sphincteric, not vocal, and the question arose as to whether, in carrying out tracheotomy, the sphincteric control was too suddenly cut out. To obviate this he had devised, and had used for two years with excellent results, a simple valve, which he showed. It enabled the opening to be gradually widened by the nurse, but never to the full extent of the inside bore of the tracheotomy tube. It must be applied immediately after the tracheotomy—that is, for the period of crisis due to the change induced by the operation. Mr. V. E. NEGUS, discussing the device, agreed as to the need for immediate application. It regulated the intake and egress of air, and at the same time controlled the pulmonary circulation. If warm air were used, the advantage would, he thought, be increased, and he suggested that if springs could be attached it would be better still. Dr. P. WARSON-WILLIAMS stressed the importance of the adjustment, after the operation, of the proportion of CO_2 in the blood. Mr. STIRK ADAMS asked whether the valve was likely to be of value in chronic cases, and the PRESIDENT replied that it was specially meant for acute obstruction and the tracheotomy done for that.

Many cases were shown at Queen's Hospital, and members dined together, and afterwards attended a performance of *Henry V* at the Memorial Theatre, Stratford-on-Avon.

CANCER OF CERVIX AFTER ARTIFICIAL MENOPAUSE

At a meeting of the Midland Obstetrical and Gynaecological Society, held in Birmingham on May 14th, with the president, Dr. C. E. PURSLOW, in the chair, Mr. S. W. MASLEN JONES read a short paper on "Carcinoma of the Cervix following Production of Artificial Menopause by Radium," and described a recent case of his own.

The patient, aged 48, 7-para, had a history of increasing losses for several months; she was too fat for accurate bimanual examination or abdominal section. She was treated by curetting and intrauterine radium (2,400 mg. hours). The curettage showed no evidence of malignancy. Two years later the bleeding recurred, and she was found to have an inoperable carcinoma of the cervix, which was again treated by radium. It was too early as yet to say what the ultimate result would be.

Mr. Maslen Jones said that he regarded this case as being of particular importance in view of the increasing use of radium to stop bleeding of this type. It had the same disadvantages as had a subtotal compared with a total hysterectomy, in that it left the patient with a risk of developing carcinoma of the cervix, although the urgent symptom of bleeding was equally well relieved by any of the three methods. He did not agree that the presence of malignant disease could always be excluded by histological examination of material removed at curettings. He felt that in many cases the use of radium merely suppressed a symptom, leaving a diseased organ behind, and that if the patient was a good operative risk the method of choice of producing the menopause should always be a total hysterectomy. He also mentioned the danger of a "flare up" of latent pelvic infections after the use of radium.

Mr. A. B. DANBY thought that the use of radium in this case might have produced a stricture of the cervical canal, and the carcinoma developed as a result of irritation by pent-up discharge. Mr. H. L. SHEPHERD said he had known a carcinoma of the body of the uterus develop two years after the use of radium for menopausal bleeding. This case was successfully treated by panhysterectomy. He thought, nevertheless, that radium was definitely indicated in most of these cases, as the bleeding was due to abnormal ovarian activity, which was directly destroyed by radium. Mrs. BERTRAM LLOYD said that even total hysterectomy was no sure guarantee of safety for these cases, as she had known a carcinoma develop in the vaginal vault twenty years after total hysterectomy. Mr. MASLEN JONES, in replying to the discussion, said that the cervix appeared to be healthy when he first applied the radium. He thought that the deeper layers of the endo-

metrium, which were essential for a diagnosis of malignancy, were often left behind when curetting.

Obstetrical Rarities

Mrs. BERTRAM LLOYD described a case of recurring inversion of the uterus.

The patient was a 1-para, aged 24, in whom the inversion occurred before separation of the placenta. Her doctor peeled off the placenta, replaced the uterus, and sent her into hospital. On admission she was very shocked, and the fundus of the uterus was at the level of the umbilicus. Puerperium was normal until the fourth day, when the fundus of the uterus again appeared in the vagina. It was replaced under an anaesthetic with great difficulty, and kept in position by an intrauterine pack. The rest of the puerperium was normal.

Owing to improvements in obstetrical technique inversion of the uterus was becoming much rarer, and had a lower mortality rate. Mrs. Bertram Lloyd thought that in her own case the inversion was not replaced fully at the first attempt.

Mrs. Bertram Lloyd described also a case of quadruplets occurring in a 2-para aged 23. The condition was diagnosed radiologically; the patient had a mild toxæmia in the later weeks.

Labour started about one week before term, and the patient delivered herself rapidly of four living male children, three of which had one placenta, the presentations being footling, vertex, shoulder, and breech. The total weight of the babies was 16 lb. 14 oz., and of babies and placenta 20 lb. 10 oz. The first stage of labour was painless, and of unknown length. The second stage lasted three hours twelve minutes, and the third stage eighteen minutes. One child (the largest) died next day, but the other three did well. The mother had a normal puerperium.

Miss B. M. WILLMOTT described a case of contraction ring recurring in successive labours in a 2-para aged 29.

At the first labour at term, fifteen months previously she was sent into hospital on account of obstructed labour due to a contraction ring gripping the neck of the child. The second labour, also at term, was normal until the head showed at the vulva, when no further advance occurred, and exploration of the uterus showed again a ring gripping the neck. The treatment adopted was lower segment Caesarean section through a vertical incision. Mother and child recovered normally.

AN EPIDEMIC OF PUERPERAL FEVER

At a meeting of the North of England Obstetrical and Gynaecological Society at Leeds, on May 11th, with the president, Professor DANIEL DOUGAL (Manchester), in the chair, Mr. D. W. CURRIE (Leeds) gave a report on a recent epidemic of puerperal fever, with notes on some cases of puerperal peritonitis.

The epidemic, he said, had lasted from the end of February to the middle of March, and was due to a haemolytic streptococcus. Ten women were affected, and four died. Of the patients recovering, one had a positive blood culture and another peritonitis. As a result of his investigation Mr. Currie found that: (1) The hospital was over-full for several days, the average daily in-patients being about 120 for 108 beds. The number of patients in the labour department varied from nine to fifteen for ten beds. (2) Three patients were in the labour department for over three days, and were frequently moved from the first-stage ward to the labour ward and back: although the linen was changed at each move it was possible that a septic patient soiled more than one bed. This danger was obviously apt to occur in a large central labour ward such as the one involved, which has six beds. (3) One definitely septic patient was taken after delivery to a clean lying-in ward. She should have been sent to the isolation block, or at any rate to a side ward. (4) There was often delay in transferring feverish patients from the large lying-in wards to the side wards. This was due to the difficulty of managing the beds owing to overcrowding, but probably explained the infection of the two last patients, both of whom developed peritonitis, which proved fatal in one case. Commenting on the seriousness of a contact epidemic, Mr. Currie deprecated the practice of admitting "failed forceps" and other

probably infected cases into the labour ward with clean cases. He also stated that the blankets and the bed-pans had come under suspicion as possible vehicles of contagion.

Mr. CURRIE then gave a brief account of seventeen cases of puerperal peritonitis operated on by him in the last four years. Clinically they were divisible into three groups: (1) peritonitis following abortion, (2) atypical peritonitis occurring early in the puerperium, and (3) typical peritonitis appearing late in the puerperium. In the atypical group there were nine cases with one recovery. The most constant signs were distension and free fluid. Other points were sudden rise in temperature and pulse rate, slight superficial tenderness, and diarrhoea. The treatment in each case was laparotomy and drainage. The fluid in the cavity was usually serous, with pus flakes in the pelvis: until lately a tube had been left down to the pouch of Douglas and removed after three days. Subsequent drainage was slight, yet post mortem the peritonitis had advanced to the stage of localization. Latterly the tube had been inserted just into the cavity and left for a week; this was done in the patient who recovered, and thin, serous fluid drained for three or four days, then changing to thick pus. Another patient was operated on on the third day, after complaining of severe abdominal pain. She had typical signs of appendicitis with peritonitis, and the appendix was gangrenous; she recovered. Three patients late in the puerperium had signs typical of peritonitis. All three had local abscesses, and recovered after drainage. Four cases were post abortum. This class was less dangerous, because the infection tended to be limited to the pelvis. Two were drained by posterior colpotomy, and recovered; two patients died after abdominal drainage.

Dr. T. N. A. JEFFCOATE (Liverpool) read a paper entitled "Endometriosis as a Manifestation of Ovarian Dysfunction"; Mr. A. GOUGH (Leeds) described a case of menstruation starting at the age of 29; Mr. W. GOUGH (Leeds) showed specimens of a double monster, and gave an account of a large cervical fibroid which had obstructed labour; and Dr. E. A. GERRARD (Manchester) read a communication on dystocia due to rigid cervix following colporrhaphy.

CAESAREAN SECTION

At a meeting of the Edinburgh Obstetrical Society on May 9th, with the president, Dr. OLIPHANT NICHOLSON, in the chair, Drs. HAULTAIN, ROBERTSON, and DEWAR contributed a paper on a study of Caesarean section. The authors stated that 463 cases would be considered altogether, with special reference to the late results of 174 operations, this being the number of answers received from a questionnaire sent to all patients who had a Caesarean section operation performed at the Royal Maternity Hospital, Edinburgh, during the years 1925-31, inclusive. Indications and immediate results were shortly dealt with. Attention was then drawn to the late results in regard to the effect that the operation seemed to have on the general health of the mother and child, on the menstrual function, fertility, pain, and bladder or bowel dysfunction. It was found that the general health of the mother was usually excellent in the years following the operation, and only 10.9 per cent. stated that they were not in good health, but as a number of these women suffered from cardiac disease a degree of bad health was only to be expected. The general health of the babies was good, and compared very favourably with the Registrar-General's statistics of infantile death rate from 1 month to 5 years. In regard to menstruation it was found that only 15 per cent. suffered from any abnormality of their periods, but it was interesting to note that the cases of amenorrhoea and scanty menstruation following the operation were as common as those of menorrhagia. Dysmenorrhoea was present in 7.5 per cent. of cases, and was chiefly premenstrual in type. The most interesting result of the investigation, however, was the fact that in 62.7 per cent., where operation could have been followed by a pregnancy, no pregnancy resulted. This seemed to be a very high sterility rate, which was difficult to account for. The fact that

fourteen patients were delivered naturally for the pregnancies following Caesarean section showed that the old saying "Once a Caesarean, always a Caesarean" was by no means the case in this series. Pain was found to be present and to be probably or possibly due to the operation in 19.6 per cent. of cases, but in only 8 per cent. was the pain sufficient to make the patient seek medical advice. Urinary symptoms were present in 12.8 per cent. of cases, the predominant complaints being frequency and painful micturition. Constipation was prevalent as a new symptom in 12 per cent. of the patients operated upon, and could be traced as a cause of pain in a number of the patients who complained of such. The question of Caesarean section being done in first or second pregnancies when alternative methods of treatment might be considered was discussed fully, especially with regard to the fact of the low fertility rate following such an operation.

Non-infective Vaginal Discharge

Drs. CRUICKSHANK and SHARMAN (Glasgow) then gave a communication on vaginal discharge of non-infective origin. They stated that an excessive discharge per vaginam might arise from any one of three sources—vagina, cervix, or uterus. The tubular glands of the endometrium were the source of a small quantity of watery and highly alkaline secretion from the normal uterus. The secretion from the racemose glands of the cervix was thick, mucoid, normally small in amount, and definitely alkaline, the pH ranging from 8 to 9. This normal vaginal "secretion"—not a true secretion, as there were no glands in the vaginal epithelium—was white, cheesy, highly acid in reaction, and consisted of epithelial squames, Döderlein's vaginal bacilli, some transudate, and lactic acid. The lactic acid, which was responsible for the high acidity, resulted from the breaking down of glycogen in the vaginal epithelial cells, probably by bacterial action. These conditions were found in the vagina during reproductive life and for a short period after birth, when glycogen was also present in the vagina. The deposition of glycogen there was probably controlled by the oestrogenic hormone. In the study of a series of cases of leucorrhoea in virgins it was thought that a bacteriological and chemical study of the discharge might afford a basis for diagnosis in the investigation of its nature and source. As a result of the laboratory examination they were able to classify a series of over forty cases of vaginal leucorrhoea into two categories—(1) infective and (2) non-infective. The infective group were mostly infections with *Trichomonas vaginalis*. Among the non-infective cases hormonal disturbance was often strongly suggested, either by the individual's "make-up" or by gross menstrual dysfunction. Spontaneous remission of the discharge tended to occur at intervals. The average age at onset was low—19 years. Sometimes the complaint dated from puberty, and in three of the series excessive discharge was noted before menstruation had begun. In four out of five cases examined excess of oestrin was present in the urine, while radiological examination showed diminution of the sella turcica in three out of five cases. On vaginal examination no lesions, inflammatory or otherwise, were discovered. The laboratory findings, which included microscopical study of a fresh drop of the vaginal secretion in saline, estimation of the hydrogen-ion concentration by means of the capillator indicator (British Drug Houses), and repeated examinations of smears and cultures from the vagina, cervical canal, and uterine cavity were summarized as follows:

	Non-infective	Infective
Secretion...	Whitish, viscid, cheesy	Gray-yellowish (fluid, frothy)
Smear ...	Grade I flora (epithelial cells and Döderlein's vaginal bacilli)	Grade II or III flora (pus cells trichomonas and mixed bacterial flora)
Culture ...	Döderlein's bacilli	Profuso, mixed
Reaction (average pH)	4.4 (4.2 to 4.7)	5.6 (4.9 to 6.0)

Drs. Cruickshank and Sharman pointed out that excessive discharge of non-infective origin might occur in non-virginal patients, and its occurrence in pregnancy was very common.

CORRESPONDENCE

Memorial to Sir Walter Fletcher

SIR.—The public life of this country suffered a loss of more than common magnitude through the death of Sir Walter Morley Fletcher, K.B.E., M.D., F.R.S., first Secretary of the Medical Research Council, on June 7th, 1933. He was then in his sixtieth year and in the height of those powers which he had used without stint in the service of science and of mankind. The ideal that he held before him, in words which were frequently upon his lips, was the advancement of knowledge for the relief of human suffering. He strove ever towards this, both in his years at Cambridge as a brilliant investigator and an influential teacher of youth, and later in the administration of the public support provided for medical research and in measures for bringing the results of scientific work more effectively to the assistance of the State.

Walter Fletcher gave richly to the common weal, and it is proper that some worthy tribute of an enduring kind should be paid to his memory. The desire to take part in this will be widespread among those who were able truly to appreciate his great labours in the cause of medical science, and will be felt not least by the many research workers who were directly indebted to him for help and inspiration: it will extend, also, to others in different spheres of life who were privileged to enjoy that friendship for which he had so great a gift, and throughout a wider circle of those who admired his vigorous personality and his mastery of practical affairs.

It is considered that the tribute should consist in the first place of a personal memorial, and, secondly, of the inception of some scheme for the furtherance of the cause which Sir Walter Fletcher had so much at heart. It is therefore proposed first to commission a portrait bust, to be placed in a suitable setting in the entrance hall of the National Institute for Medical Research at Hampstead. The remainder of the sum collected will then be used as a fund for building—at the farm premises of the National Institute at Mill Hill—a Walter Fletcher Laboratory, to be devoted particularly to those nutritional studies in which he was so keenly interested. This will not only provide an appropriate memorial, but it will make an urgently needed contribution to the national equipment for work in what is at present among the most important of all branches of medical research.

In view of the wide utility and public value of the second part of the memorial, it has not been thought desirable to suggest for individual subscriptions any limit such as might have been fitting for a tribute of a purely personal character. It is strongly hoped, however, that this will in no way deter those who may wish to have a share in the personal memorial but are of necessity restricted to giving quite small sums. All subscriptions should be sent to the Secretary, Fletcher Memorial Fund, 38, Old Queen Street, Westminster, S.W.1.—We are, etc.,

Classification of Mental Disorders

SIR.—You published on June 2nd two pages relating to the classification of insanity, together with its introduction and an accompanying commentary. May I ask you for space for a personal criticism? I may state that I was the honorary secretary (ten years) of the Medico-Psychological Association, which covers the period in which the old classification of mental disorders—now to be discarded—was propounded. I was also the lecturer on mental diseases (fifteen years) to St. Bartholomew's Hospital, and before that (three years) at the Westminster Hospital, and I therefore claim to write with some experience.

The classification of insanity has always been a difficult task, because the phenomena of defect or disease implied by the term impress most students of mental diseases differently. So much is this the case that every teacher has produced a classification of his own, sooner or later to be varied or abandoned as an unsolved jigsaw puzzle. To one observer the most important matter is whether the patient will get well or not, and the classification to him (representative of many general practitioners) is into curable and not curable. Even to-day the weekly report of the resident physician of a well-known mental hospital to his committee is that so many of the patients are curable, whilst so many are incurable. The seriousness or the severity of the attack has also given rise to a classification into benign and malignant or into acute and chronic, whilst the element of time—namely, recent and chronic—has also been employed to qualify the form of insanity.

A pathological classification based upon changes in the brain would naturally be the ideal and logical one. We know what the exact underlying pathology of diphtheria, pneumonia, consumption, general paralysis, and lockjaw may be, and the treatment is adopted accordingly, but up to the present time we have found no scientific correlations between morbid cerebral and morbid mental states.

A classification according to age or to the period of life at which an attack may occur has also been presented, as well as an aetiological one with very varied syndromes, yet such was accepted by Skae and by his pupil Clouston; but the one depending upon symptoms, and described as the "clinical," still remains—with modifications—the most acceptable scheme. As insanity is an affection of the mind influencing conduct it would appear that a psychological classification would help to separate and make clear the various departures from the normal, and many attempts have been made to secure a helpful psychological classification, but the results have been disappointing, thus leaving us with the one based upon clinical findings, which has the merit of being the only practical and understandable classification. This one, the clinical, in spite of the fact that it includes divisions which are not mutually exclusive—a fundamental necessity of every scientific classification—has obvious practical advantages. It nevertheless presents overlapping symptoms: in some of the groups, for instance, mania occurs in the delirium of toxæmia, in general paralysis, in the alternating stages of recurrent insanity, and dementia may not only be a terminal stage of melancholia and mania, but may occur as a primary and a gradually deteriorating mental state.

The classification presented in the *British Medical Journal* of June 2nd, said to have been accepted by the Royal Medico-Psychological Association, has much to recommend it, but it has a strong Continental flavour, in that much of it is the outcome of the teachings of Freud. It was his pupil Bleuler who adopted the term "schizophrenia." There is much dispute even to-day as to the exact connotation of this term, and much confusion still attaches to it. Another term, "paraphrenia" (not an affection of the diaphragm!), not only includes the acute hallucinatory psychoses in the new classification, but also all the eccentrics, and it is in no way a subdivision of the schizophrenics as is claimed.

Owing partly to the expositions of Freud and partly also to the extended experience of mental disorders acquired during the war, a desire has arisen for a more modern classification, and one is now presented with eleven divisions and several subdivisions. The first division is (A) mental deficiency, expressed in English, Greek (oligophrenia), and Latin (amentia), but to be used preferably in Greek. The term "oligophrenia" was advocated thirty-five years ago by Andriezen, but was not accepted, and many ailments possess elementary, though arrested, minds. I am of opinion that teachers and medical superintendents who will be responsible for compiling the future statistics would naturally prefer the English equivalents, which would also be in harmony with the legal definitions of the Mental Deficiency Acts, 1914 and 1927.

I pass over the second division (B), merely remarking that the Mental Treatment Act, 1930, which sanctions the reception of voluntary boarders, will need an extension of the class "neuroses and psychoneuroses." The anxiety states (b) might well include states of doubt, anger, and fear, for it is certain that many cases will come under this group. Also compulsions (c) would be more comprehensible as impulses, thus recognizing the pathological affections of the will; for conduct is the result of the struggle between the impulse to act and the will-power to control the act.

The third division (C) is entitled "schizophrenic psychoses" and includes paraphrenia, a term which requires a fuller definition than is implied in the term "schizophrenia." Kraepelin (its inventor) defined paraphrenia as a disturbance of the intellect with but little interference with or affection of the will and feeling. As already stated, the term is wide enough to include the oddities, singularities, and the fantastic persons we meet, and its significance is no more a splitting up of the mind than is schizanthus (applied to a leaf) a splitting up of the flower. The schizoid group, by some authorities, is even made to represent the arrest of intellectual development described as idiopathic idiocy. Paraphrenia, if included at all, might be more aptly classified under the fourth division (D) psychopathic constitution, an indefinite heading, which would be more clearly and better defined under delusional insanity; (a) systematized, (b) unsystematized—a term sanctioned by long usage and described in every English textbook, but which disappears in the new terminology.

The fifth division, (E) affective psychoses, might also be better described as the emotional psychoses, with subdivisions into (a) mania or exaltation, (b) melancholia or depression, and (c) recurrent or alternating forms, so there would be no need for the Greek term "cyclothymia."

The tenth division, (J) dementia, in my opinion needs subdividing into (a) primary and (b) secondary or terminal. Dementia praecox is preferred by many practical alienists as classified under dementia rather than under the so-called schizoid group.

I regret to find that the term "delirium" is omitted from the classification. It is the earliest and most invariable symptom of confusional insanity, and should be bracketed under (F) confusional states.

Apart from the uneasiness, and even the fear, which many medical men (and others) entertain about introducing the Greek gods and heroes into their patients' families, whether they be Oedipus, Electra, Narcissus, or any other, I fail to see the necessity for complicating an English terminology with the use of classical names when the English equivalent can express the full meaning equally well. Also, it would be absurd and unreasonable to expect students of mental disorders to diagnose a case of mental disease in hieroglyphics, such as "E a ii . 8 b c & 1 a," as is suggested, and I trust the new classification may be amended before it is finally accepted as *ex cathedra* with the sanction of the Royal Medico-Psychological Association. I have trespassed at such length upon the hospitality of your columns that I shall refrain from the infliction upon your readers of proposed criticisms on Part II of the classification, as I had intended.—I am, etc.,

ROBERT ARMSTRONG-JONES,

London, June 9th

Psychological Effect of Hysterectomy

SIR,—I was much interested in Dr. Winifred Coppard's letter under the above heading in the *Journal* of June 9th (p. 1048), and would refer her to my Hunterian Lecture on "Myomectomy" (*Lancet*, 1931, i, 171). Therein I discussed the psychological effects of hysterectomy, and pointed out the grievous results that may follow it in certain cases.

For many years I have strenuously advocated myomectomy in preference to hysterectomy in all those cases in which the removal of the uterus is liable to be followed by undesirable psychological effects. Conservatism on these grounds is most certainly desirable in nearly all cases of fibroids under 40 years of age, and in a certain number over that age. By the technique which I now employ I find it possible to conserve any uterus, irrespective of the number and position of the fibroids, and that without an operative risk greater than that of hysterectomy.—I am, etc.,

London, W.1, June 8th.

VICTOR BONNEY.

Value of Auscultation in Acute Abdominal Conditions

SIR,—I was glad to read Mr. T. G. Illtyd James's remarks on the value of auscultation in his interesting article, "Observations on the Acute Abdomen," published in your issue of June 9th. He revives a method of examination suggested by Robert Hooke¹ in 1705, when he wrote "that it may be possible to discover the Motions of the Internal Parts of Bodies . . . by the sound they make that one may discover the works performed in the several Offices and Shops of a Man's Body and thereby discover what Instrument or Engine is out of order, what works are going on at several times and lie still at others."

The first accurate observations on the rhythmical sounds of the stomach and small intestine were published by Cannon² in 1905. Two years later I published in the *Guy's Hospital Reports* some work carried out with the help of F. Cook, A. Neville Cox, H. Gardiner, E. G. Slesinger, and A. H. Todd,³ then students at Guy's, which showed that the sounds heard over the caecum as a result of the passage of fluid faeces from the terminal ileum through the ileo-caecal sphincter undergo definite variations in the course of the day. The clinical application of the knowledge thus gained on normal individuals led me to publish a paper in the *British Medical Journal* for November 28th, 1908, on "Abdominal Auscultation as an Aid in Diagnosis."

Two points only are worth adding to Mr. Illtyd James's observations. The first is that in peritonitis the sounds disappear in the neighbourhood of the lesion before they disappear from the rest of the abdomen. Thus gastric sounds continue after the complete disappearance of caecal sounds in peritonitis resulting from a gangrenous appendix, and sounds may persist for a short time after the perforation of a gastric ulcer, though the stomach sounds have completely disappeared. In duodenal perforation, however, the caecal sounds disappear as early as the gastric sounds, owing to the tendency of the escaped material to pass towards the right iliac fossa.

The second point is the importance of the sudden disappearance of caecal sounds as evidence of perforation of a typhoid ulcer; the lesion is almost always in the neighbourhood of the ileo-caecal junction, so that perforation leads to reflex paralysis of the terminal ileum

¹ Hooke, R.: *Method of Improving Natural Philosophy*. London, 1705, p. 39.

² Cannon, W. B.: *Amer. Journ. Physiol.*, 1905, xiv, 339.

³ *Guy's Hospital Reports*, 1907, lxi, 389.

and spasm of the sphincter. I referred to a case of typhoid fever in which I had auscultated over the right iliac fossa at each visit and had always heard the typical caecal sounds. The patient, who was very ill, complained one day of abdominal pain. His pulse was found to have risen slightly, but the temperature was unaltered. There was a slight increase in the rigidity of the abdominal wall, but no distension. I saw him two hours after he first complained of pain. No caecal sounds were heard on listening for two minutes, although occasional gurgles were still audible in other parts of the abdomen. A perforation was diagnosed, and at the operation two were found in the ileum within an inch of the caecum, and spreading peritonitis was present.—I am, etc.,

ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest, June 11th.

Diverticulitis

SIR.—Mr. Harold Edwards, in his clinical review of diverticulitis (*Journal*, June 2nd, p. 973), rightly says that "the role of the surgeon in the treatment of diverticulitis is largely confined to the treatment of its complications." He then mentions five cases in which a radical type of operation was performed, four of which "were progressing dangerously towards one of the complications"—namely, obstruction, perforation, abscess, and colo-vesical fistula. Any case of acute diverticulitis may be complicated in one of the four ways mentioned, and it becomes a nice point in surgical judgement to decide in any case whether the danger is sufficiently great to justify an operation. Fortunately, the great majority of cases, if treated by medical measures on the lines laid down by Dr. Spriggs—whose writings on this subject might with advantage have been included in Mr. Edwards's somewhat meagre bibliography—will clear up without any operation.

A more serious difficulty, in my experience, lies in the diagnosis, and a surgeon may open the abdomen in a case of acute diverticulitis under the mistaken impression that he has to deal with a leaking growth or an acute pelvic appendicitis. The very fact of exploring the abdomen adds a new factor—the probability of post-operative distension. In the presence of a potentially obstructive lesion at the lower end of the colon, post-operative distension may lead on to a dangerous ileus. These cases, like those somewhat vaguely labelled by Mr. Edwards as "progressing dangerously towards one of the complications," demand a further surgical measure. Mr. Edwards recommends a permanent type of colostomy, to be left open for a minimum period of twelve months, and condemns a caecostomy except as a possible prelude to the radical operation. He says: "Apart from the distress it causes the patient, caecostomy gives only very imperfect drainage to the colon, and has a very limited effect upon the inflamed distal portion"; and he quotes one case in which a recurrent attack of acute diverticulitis occurred fourteen days after caecostomy had been performed. He does not tell us what use was made of the caecostomy. I agree with Mr. Edwards that a temporary caecostomy gives imperfect drainage to the colon, for which reason I never now use it as a prelude to a radical operation either for a growth or for diverticulitis of the descending colon. But my experience teaches me that when used as a safety-valve against obstruction, as a means of lubricating the large intestine with paraffin, and when combined with the medical regime laid down by Dr. Spriggs, temporary caecostomy is the operation of choice in the group of cases under discussion. I venture to think that the distress caused to a patient

by a temporary caecostomy, which need not be left open for more than three weeks to a month and which heals spontaneously within a few days of removing the tube, is infinitely less than that of a permanent colostomy, which is to be left open for a minimum period of twelve months and requires a second operation to close it.—I am, etc.,

Reading, June 6th.

J. L. JOYCE, F.R.C.S.

Hyperpiesia

SIR.—I have read with much interest Dr. C. P. Donnison's article in the *Journal* of April 21st (p. 704), on "The Cause of Hyperpiesia," and must congratulate him on the exceedingly able way he has set out his thesis. At the same time I do not think his vision is all-embracing of the subject.

Any conception of hyperpiesia as due to the vaso-constriction action of a hormone must take cognizance of the vaso-dilating complementary hormone or hormones. Cannon's emergency reaction, as being associated with an overplus of adrenal activity, does not satisfy one.

Adrenaline is produced by the appropriate glands, but new work referred to by Dale in a recent number of the *Lancet* informs us that a product which is either adrenaline or something biochemically indistinguishable from it is liberated from all sympathetic nerve endings when these nerves are stimulated. Furthermore, Dale states that the direct antithesis to adrenaline—to wit, acetylcholine—is liberated at the vagal nerve endings when these are stimulated. Acetylcholine is a very valuable vaso-dilator in addition to being a stimulator of bowel activity in contradistinction to the paralysing influence of adrenaline.

Cannon's response can only satisfy one if the emotional stress (1) both stimulates the sympathetic and depresses the vagotonic systems, or (2) depresses the vagotonic only, allowing unbalanced sympathetic activity. In these ways one can explain the difficulty of detecting extra circulating adrenaline blood content.

There may be no excess but simply a lack of the acetylcholine buffer, and this may not be a temporary state secondary to mental stress, but a continuous one acting over years. Only in this way, to my mind, can physiological quantities of adrenaline produce what we loosely term "essential hypertension." Acetylcholine may not be the sole agent involved. Vagotonine, a pancreatic vaso-dilator, may be at fault, or adenosine, the vaso-dilator described by Dale as present in all muscles (where vaso-dilatation is such an asset) in abundance. Kallikrein must also be considered produced, I believe, when the blood is acidified.

Dr. Donnison's article is of great interest, but I feel that while hypertension may spring from root causes such as he describes, the net result produced from these causes is an imbalance between vaso-dilator and vaso-depressor activities, and, decidedly, this does not necessarily imply an over-production of the latter substances. Unbalanced physiological quantities will suffice.—I am, etc.,

J. DRUMMOND, M.D., F.R.C.P.Ed.

Durban, S. Africa, May 22nd.

SIR.—In the *Journal* of May 19th (p. 919) appears a letter from Dr. Herbert Brown in which he states, *inter alia*, his opinion that alcohol is not a contributory cause in hyperpiesia. This is not the generally accepted view, and many patients are ordered to abstain from alcohol in any form, which removes another of the few pleasures left to advanced age. I have waited in vain to see some

of your many readers join issue with Dr. Brown on this matter, and I would be glad to learn whether or not the profession accepts the accuracy of his observations.—I am, etc.,

London, W.C.1, June 5th.

GRAHAM GRANT.

Silicosis in India

SIR,—With reference to the leading article on silicosis, in the *Journal* of April 14th (p. 676), I wish to inform you that recently the Mysore Government appointed a special committee, consisting of the chief medical officer of the Mining Board Kolar Gold Fields, the local medical officer of the Mysore Government, and the physician of the Krishnarajendra Hospital, Mysore, to investigate the question of the prevalence of silicosis among the miners in the Kolar Gold Field area. The committee conducted a preliminary investigation, and unanimously arrived at the conclusion that silicosis does occur among the underground workers. Through the courtesy of the managing agents—Messrs. John Taylor and Sons, London—the available material was submitted to Dr. L. G. Irwin, chairman of the Miners' Phthisis Medical Bureau, South Africa, for opinion. Dr. Irwin, after a careful examination of the material supplied, has come to the conclusion that the pathological and radiographic evidence "appears to create a *prima facie* case that instances of silicosis do occur among the underground workers in the Kolar Gold Fields."

The committee is, however, of opinion that the incidence of the disease in the Kolar Gold Field is much smaller, and that it takes a much longer time to develop signs and symptoms, than in South Africa. This is evidently due to the fact that the percentage of free silica contained in Kolar rock is 5 to 20, as compared with the much larger percentage of 43 to 98 obtaining in South African samples. Further investigation is in progress. Under the circumstances I feel it necessary to contradict the statement made in the article referred to that "in the Kolar Gold Field, India, where the rock contains a large amount of quartz and sericite is absent, silicosis has hitherto inexplicably been unknown."—I am etc.,

S. SUBBA RAO,

Bangalore, May 21st.

Senior Surgeon, Mysore Government.

Pituitary Enlargement

SIR,—The recent work upon the pituitary gland and its surroundings, and your informative leader in the *British Medical Journal* of October 28th last, "The Hypothalamus and the Pituitary," induce me to send you some notes of a case of pituitary enlargement which caused a condition of gigantism and blindness, the latter recovered from with dramatic suddenness.

A coloured boy of 10½ years was led to my rooms on August 3rd last by his mother, who told me that for three years he had been getting dull and stupid, and frequently fell asleep. His vision was reduced to counting fingers at two metres with the right eye; the left eye could not tell light from darkness. He was very dull and listless, and seemed much too big for his age. Height, 5 ft. 1½ in.; weight, 104 lb. Admitted same day to hospital, and head x-rayed the afternoon of following day. The picture showed marked enlargement of the pituitary fossa.

Next morning the aspect was changed completely to brightness, and he said he could see well and wanted to go home. His vision had returned to 6/60 left eye. Wassermann reaction negative both for blood and for cerebro-spinal fluid, and urine normal. Three months later he looked in excellent health. Right vision = 6/12; left vision = 6/9. Fields of vision full.

Present condition: Headaches troublesome for some weeks; increased somnolence. Said to be "lazy, and won't listen." Right vision = 6/24; left vision = 6/9. Pupils active, fields full. Fundi show a certain amount of optic atrophy, noticeable mostly to the temporal side of disks. Knee-jerks very feeble. Weight 125 lb., height 5 ft. 4 in., and looks like a well-set-up boy of 15 or 16 years.

From a study of available literature prognosis seems unfavourable. A ruptured cyst would account for the dramatic change which followed the use of x rays.—I am, etc.,

E. A. SEALE,

Grahamstown, S.A., Ophthalmic Surgeon, Settlers' Hospital.
April 27th.

Criticism of Ante-natal Work

SIR,—I have read and re-read Mr. A. J. Wrigley's most able article in the *Journal* of May 19th, and feel I should like to comment thereon.

As I happen to have the privilege of conducting the ante-natal clinic at the Christiana Hartley Maternity Hospital in the Borough of Southport, I feel that, with others, I come under the lash of his censure, but I am still of opinion that the ante-natal period of midwifery is all-important, and if this work be conscientiously carried out it can result in nothing but good for all concerned. From the replies to his article, on May 26th and June 2nd, I think he must have produced an impression different from that intended.

My experience of ante-natal work—which is, of course, very small—has impressed me in two ways: (1) the need of constant practice necessary for gaining any information from abdominal palpation, and (2) the need of an infinite amount of patience in dealing with it. I do not think it is fair to expect that a general practitioner or midwife with, say, fifty cases a year—and that is above the average, I think—could, on palpation, say with much assurance what was the lie of the child in many cases. Therefore, I maintain that at the ante-natal clinic, with constant and regular practice, this art is much more likely to be acquired. A local colleague once said to me that it was absurd to say I could diagnose an occipito-posterior position from abdominal palpation, and that the late Professor Leith Murray said he could not. I met Professor Leith Murray some time after and asked him if that were correct. He said: "Yes, it is. I used to be able to do so when I was constantly doing ante-natal work, but even after my summer holiday I came back to it feeling strange, and now that my work is chiefly gynaecological I cannot do it."

As regards the toxæmias, just a word of explanation is required on a point here. Mr. Wrigley states:

"That eclampsia is certainly not a preventable disease, however, is suggested by a recent case at St Thomas's Hospital. A primigravida was examined at 10 o'clock in the morning. She felt perfectly well, and urine and blood pressure examinations showed no abnormality. Eight hours later she had an eclamptic fit."

Does this prove the point? Does preventive maternity start *after* symptoms have developed?

Minor degrees of disproportion raise another question. To my mind a decision on what to do with the borderline case is very difficult. I think the assumption Mr. Wrigley credits us with is rather extreme. Rather let him say that from our conscientious examination of the case, failure to induce *may* be disastrous to mother and child. Therefore, after mature deliberation, and as the foetal head increases a good deal in diameter in a week or a fortnight, we will take what appears to us, appreciating the risks involved, to be the safer course and induce by the stomach-tube type of bougie. It is more conservative

for the baby and probably offers less risk to the mother than craniotomy. Here Mr. Wrigley quotes Professor Browne. I see also that the former holds his F.R.C.S. Has he never operated on a case of "appendicitis" with a healthy appendix? It is human to err, but because of that one mistake is he going to refuse to remove his next patient's appendix, which is possibly diseased, so that the cause of death is entered in the right column? Ante-natal work is in its infancy compared with surgery, and yet an error in judgement under most exacting circumstances is considered such bad practice that a suggestion for its suspension is recommended.

Finally comes the problem of external cephalic version. Mr. Burns, in a recent paper, condemned this as a routine, and I think Mr. Wrigley does the same, the main reason, so far as I can gather, being the danger of separating the placenta. The latter quotes a case where the foetal heart was heard before version and a macerated foetus was the result. Was the foetal heart not heard or listened for after version? Was auscultation of the foetal heart not performed between version and maceration? Can the placenta be detached during version without causing haemorrhage? Is it not possible in doing version to twist the cord round the babe? I have no authority for saying so, but I suggest that this is a possible cause of asphyxia of the child, particularly during delivery, although no violent or prolonged efforts at version have been made, and no anaesthetic used. In my ignorance, probably combined with good luck, I thought separation of the placenta during version was a textbook hog. I wonder if Mr. Burns or Mr. Wrigley has ever experienced it.—I am, etc.,

Southport, June 5th.

A. S. GARDEN, M.D.

Prevention of Puerperal Sepsis

SIR,—May I be allowed to point out an error which appears in the interesting article "Prevention of Puerperal Sepsis in General Practice" by Dr. W. H. F. Oxley in the *British Medical Journal* of June 9th. In quoting a paper of mine (*Lancet*, September 14th, 1929) he states that "at Guy's Hospital in the years 1863-75 there was intervention in 1.35 per cent. of all labours, whereas in 1928 the rate was 18.6—fourteen times as much." The reference should read as follows: "whereas in 1928 the rate was 8.86—about seven times as much." Although this error does not make any essential difference to the argument which follows in his paper, I am sure that Dr. Oxley would not wish this obvious slip to pass without correction.—I am, etc.,

London, W.1, June 9th.

G. F. GIBBERD.

Capacity for Work after Fracture of Spine

SIR,—In reply to Mr. Paul Bernard Roth's inquiry in your issue of June 2nd, the twelve cases I referred to in my series of 270 as doing their ordinary work were injured as follows: six had wedge fractures; five had comminution of bodies; one had a wedge fracture in addition to several transverse processes. These men were, or had just been, doing their old work at the time of my examination during the five years in which my statistics were made. There were probably many more who by now have resumed their old work, but I have no figures available to show how many.

My experience has been similar to Mr. Roth's—namely, that only a few of the patients with comminuted fractures resume full work, but where there is only a simple wedge fracture quite a number do so.—I am, etc.,

Cardiff, June 6th.

OWEN L. RHYS.

Osteopathy

SIR,—I have read with interest the letter of Mr. A. S. Blundell Bankart (May 19th), and I think that medical men should be further acquainted with the truth about this movement. The Registration and Regulation of Osteopaths Bill not only seeks to place osteopaths on a register, but to give them all the privileges of a medical practitioner. They will have power to sign certificates of birth and death. They will be allowed to administer anaesthetics and perform "minor operations." They will also enjoy the medical man's privilege of exemption from jury service. The period of study for qualification as an osteopath is given in the Bill as 4,422 hours. It would seem that one could qualify in about two years. I agree with Mr. Bankart that this appears to be an "American stunt." The passing of this Bill would produce a third-rate medical service, which might well prove a serious danger to the public weal.—I am, etc.,

Louth, Lincs, June 9th.

RALPH MORTON, F.R.C.S.

SIR,—A short time ago I saw a patient who, after an accident, had been treated by an osteopath for a "displaced bone" in the spine. The "highly developed tactile sense" of the osteopath revealed to him a displaced sixth cervical vertebra—a displacement not visible by x ray—but failed to reveal a fracture of the transverse process of the third—easily visible by x ray.—I am, etc.,

London, W.1, June 11th.

F. A. BEARN.

Junior Appointments in a Mental Hospital

SIR,—The following notes, made four years ago at the end of nine months in a temporary appointment which I secured in a mental hospital in order to obtain some special experience of mental disease and its treatment, may have a certain value commonly ascribed to first impressions: in any case I hope they may prove of interest to young medical graduates who are wondering what to do next.

In general municipal hospitals junior medical officers, being clinicians almost exclusively, have in certain respects more fascinating employment than their seniors, whose daily task includes much routine administration. In mental hospitals, on the contrary, so far as my experience goes, there falls to the junior medical officer only the duller work. All new cases are admitted into certain special wards under senior officers; this arrangement, most advantageous, and perhaps essential for the patients' welfare, militates strongly against the junior doctors. It is difficult to develop the keenest clinical interest in general medical or surgical cases whose notes and preliminary treatment have been already dealt with fully by a colleague; it is even harder to acquire such interest in mental patients who, after a variable time in the admission wards, have been segregated into the chronic wards, where but a small proportion of the patients are of recoverable type. So far as my experience goes, these chronic wards only are allocated to the junior members of the medical staff in a large mental hospital.

To the beginner with a flair and enthusiasm for mental work these conditions cause but slight discomfort. Chronic wards mean easy duties, which provide ample leisure to observe interesting cases in other wards, thus furnishing wide experience of mental disease as it exists in mental hospitals. Moreover, he must prepare for the D.P.M., without which he is ineligible for promotion. His clinical ardour therefore finds sufficient sustenance during his period of waiting for wards giving responsi-

bility for new patients. But such enthusiasts are in the minority in the personnel entering the mental-hospital service. I suggest that many men, though without special interest in mental work, might advisedly enter the service on a temporary basis. I refer in particular to men who, while reading for higher qualifications, require to hold a bread-and-butter appointment, and are not averse to one offering also some experience of the neglected subject of mental disease. Apart from tea and night rounds, which occupy about twice weekly an extra portion of the orderly duty days, the ward work of the junior medical officer generally finishes before lunch; and the morning round, however conscientiously performed, is not exhausting. Since the chronic mental wards give relatively little opportunity for general clinical medicine and surgery, only men who have finished their house jobs, and require leisure chiefly for concentrated reading, are advised to take a temporary mental hospital appointment.

I maintain that this one-sided consideration of the interests of the medical graduate does not entail disregard for the chronic mental patients, for the man who earns his living while attempting to take higher qualifications seldom neglects the duties for which he is paid. Moreover, it appears impossible for large mental hospitals to keep an energetic medical staff up to its full numbers unless recruited partly on a temporary basis; certainly there are not enough suitable posts for a staff composed entirely of active men whose clinical interests centre mainly on mental work. Another point, which scarcely requires amplification, is that the greater the number of men who have held temporary mental hospital appointments the greater will be the diffusion of knowledge of mental disease (the Cinderella of medical science) throughout the medical profession, in particular among the most important group—that of the general practitioners.

I conclude with the sincere hope that, on achieving his primary object of a higher qualification, the junior medical officer who has failed meanwhile to acquire enthusiasm for mental work will make an early change from his temporary appointment to new fields: of endeavour, for, unless combined with some other absorbing interest, the light duties and pleasant life of a junior medical officer in a large mental hospital readily engender a habit of placid laziness, which in a few years too often leaves its owner in a stagnant rut.—I am, etc.,

WILLIAM G. PATTERSON, M.D., M.R.C.P., D.P.H.

Weybridge, June 4th.

The Cancer Problem

SIR,—Any theory of cancer must conform to reality. Dr. Jordan, in his letter in the *Journal* of March 3rd (p. 403), holds that our highly sophisticated diet must play a prominent part in producing susceptibility to cancer. Here he ignores a well-known fact, repeatedly stressed by the Board of Control in the blue book, that in mental hospitals the incidence of cancer is much lower than in the general population. In these hospitals, nowadays, the diet is fully up to the general standard, both in quality and in variety. In the Norfolk County Mental Hospital, where I work, the diet is certainly better than that of the class from which the majority of patients are drawn—namely, agricultural labourers—yet there are few cases of cancer. During the eleven years 1923-33 inclusive, there have been on the female side, with an average of 652 resident, 409 deaths, with only nineteen of these deaths due to cancer. The average age for the 409 deaths is 59.8 years. I imagine that with a death age as high as this the cancer incidence would be much higher among the general population. Of the nineteen cancer deaths three were due to sarcoma, the remaining sixteen being due to carcinoma, and in eight of these the site

was the gastro-intestinal tract, in seven the breast, and in one the ovary. Post-mortem examination was performed in 50 per cent. of the total deaths. Mr. Duncan Fitzwilliams (June 2nd, p. 1004) seems to hold that cancer is a necessary concomitant of advanced age; but here, and also in other mental hospitals, there are many old people and yet comparatively few deaths from cancer.

Cancer from betel chewing and from smoking clay pipes, the latter, I believe, now uncommon, are due to a known irritant, and are analogous to the industrial cancers, also due to known irritants. What we want to find is the *unknown* irritant that is responsible for the abrupt rise in the cancer death rate that occurred in the latter third of the nineteenth century, the time of the introduction of the gas ring and the electric kettle; the rise has continued ever since. The only environmental difference I know of between patients in mental hospitals and in others is that, in the former, meals are rarely eaten at more than a luke-warm temperature, and I believe that the increasing habit of repeatedly ingesting very hot meals and fluids is the unknown irritant, and that this habit is responsible for the increase of cancer in the general population.

In regard to the incidence of cancer among primitive peoples during two years' service on the Zambesi River, 1898-9, and later during three years in the Cape Province, my recollection is that the general consensus of medical opinion, both in Nyasaland and at the Cape, was that in natives living under native conditions cancer was infrequent. This point the principal medical officer of Basutoland could doubtless clear up, for in Basutoland is a circumscribed native race living under native conditions with very few Europeans, and yet with a most efficient white public medical service, which issues the equivalent of the Registrar-General's report that Mr. Fitzwilliams requires.—I am, etc.,

A. W. B. LIVESAY, F.R.C.S.ED.,

Thorpe, Norwich, June 9th.

Surgeon Captain R.N. (ret.).

SIR,—Dr. Arbour Stephens's very interesting letter on industrial cancer and blood pressure (June 2nd, p. 1003) prompts me to put forward a very vague and somewhat unscientific theory. It must be clearly understood that for all I know this theory may have been put forward by others.

I have thought for some time that carcinoma may be due to a deficiency of some substance we will call x , manufactured by the epithelial cells themselves. This substance may control the proper functioning, and even some part of the life of the cells. When, due to some damage or due to a using up of this substance in over-worked cells, x comes to an end, the growth factor then comes into force, and tries hard to manufacture more of this substance by the simple means of producing more and more cells. But this becomes a vicious circle, as the new cells developed inherit the defect, and in turn divide and divide again in a desperate attempt to find the elusive x . These cells are carried about the body, and each small deposit goes on increasing in size, and reproduces cells of the same type as their great-grandparents.

Would it not be possible to secure an extract of, say, mammary gland for carcinoma of the breast, the extract to be made from the udders of young cows that have calved once? I will leave the details of manufacture to the chemist. This extract, given to the patient in suitable quantities, might replace the used-up endogenous x , and so put a stop to the accelerating mitosis going on in the body. The main point in all this is that carcinoma may be purely a deficiency disease—not a vitamin deficiency, but a deficiency from inside the individual cell that starts the trouble.—I am, etc.,

Chmstchurch, Hants, June 7th.

EDWARD F. HUNT.

Carbon Tetrachloride Poisoning

SIR,—With reference to the annotation in the *Journal* of May 26th (p. 953) on carbon tetrachloride poisoning, I wish to point out that the statement there made—that specimens of carbon tetrachloride contaminated by carbon disulphide are extremely toxic—has no scientific authority. This question is fully discussed by me in a joint article entitled "The Toxicity of Carbon Tetrachloride and its Allied Halogen Compounds," which appeared in the *Journal of Tropical Medicine and Hygiene*, dated September 15th and November 1st, 1933. In the article referred to it is stated:

"Owing to the fact that carbon tetrachloride is produced commercially from carbon disulphide (CS_2) certain authors, apparently overlooking the well-recognized chemical and pharmacological affinities of the chlorine substitution products of the aliphatic hydrocarbon series, have suggested that the toxic effect of carbon tetrachloride depends in whole or in part on the minute traces of carbon disulphide which, owing to its origin (from carbon disulphide), it often contains, and even hypothetical and unidentified sulphur derivatives other than carbon disulphide have been postulated as the cause of this toxicity, though Dale (*British Medical Journal*, July, 1924), quoting King, categorically states that the whole of the sulphur derivatives in carbon tetrachloride exist in the form of carbon disulphide alone. These suppositions lack all scientific foundation, since:

"(1) Carbon disulphide has been used in considerable doses with safety in veterinary and human medicine, and can be added in quantities of 1 to 5 c.c.m. without ill effects to carbon tetrachloride administered to experimental animals, including monkeys.

"(2) The lesions produced by carbon tetrachloride [that is, acute necrosis of the liver and (occasionally) kidneys] are identical with those produced by other closely allied members of the chlorine substitution products of the aliphatic hydrocarbons such as chloroform (which are not manufactured from carbon disulphide and are consequently sulphur-free) and are altogether different from those produced by carbon disulphide.

"(3) There is no sulphur compound known to science which is lethal to an adult of 60 kilos in doses of 1/40,000 c.c.m., this being the amount of sulphur derivatives present in 5 c.c.m. of carbon tetrachloride purified for internal use, containing 1 in 200,000 parts of carbon disulphide as shown by the potassium-plumbite test (*British Medical Journal*, 1924, ii, 218)."

For the sake of those unacquainted with the toxicology of carbon disulphide a short account of it is reproduced below from the same article:

"Carbon disulphide . . . is a clear volatile liquid with a characteristic smell. It is extensively used in the arts as a solvent for sulphur, phosphorus, and rubber. In veterinary medicine it is widely used as a remedy for bots in horses, the dose for a horse being 20 to 24 c.c.m. It is also effective in horses against gastrophilus and ascaris, and has been used as a remedy against liver-flukes in sheep. In human medicine carbon disulphide has been used as a remedy for diarrhoea in doses of 30 c.c.m. of a 3.5 per cent. solution (equivalent to 1 c.c.m. of pure carbon disulphide), four to five times a day. It has also been used in 5 per cent. solution hourly in pneumonia and as an inhalation in tuberculosis.

"Carbon disulphide acts principally on the blood and nervous system, producing in acute poisoning haemolysis of the red blood corpuscles and unconsciousness. This action is attributed by Kobert to its power to dissolve lipoids. It has also been stated to cause methaemoglobinemia. It has no characteristic effect on the internal organs, and does not produce acute necrosis of the liver. Post-mortem examination reveals no characteristic pathological changes in the viscera but the veins are found distended with dark fluid blood.

"In acute poisoning by carbon disulphide, which is rare, there are collapse, unconsciousness, spasmodic convulsions, rapid feeble pulse, slow and stertorous breathing, lessened body temperature, cold and clammy skin, dilated pupils, and insensitive conjunctivae. A case is on record of the swallowing of two ounces (60 c.c.m.) of carbon disulphide with recovery.

"In chronic poisoning, which is found chiefly in workmen exposed to the fumes of carbon disulphide in factories, there is a complex series of symptoms, which may be divided into two stages: the stage of excitement, followed by that of depression. In the first place there is headache with indigestion, loss of appetite, nausea, and vertigo, with symptoms

of over-stimulation of the nervous system, as evidenced by voluble talking, singing, immoderate laughter, or weeping. The sensitiveness of the skin is increased, burning and creeping sensations alternating with numbness in the hands and feet. This peripheral neuritis is followed by 'foot-drop' and 'wrist-drop.' The field of vision is restricted for all colours, and amblyopia and scotomata without retinal changes are common. The red blood corpuscles are greatly diminished. Pains in the limbs are a constant feature, and some observers have recorded spasmodic contractions of certain groups of muscles. In the stage of depression there is a general anaesthesia of the skin and mucous membranes, and in advanced cases there is pronounced mental and muscular weakness."

—I am, etc.,

J. WALKER TOMB,

Director, Endemic Diseases Section,
Department of Public Health.

Cairo, June 2nd.

Ephedrine in Asthma

SIR,—Drs. J. B. Christopherson and Marjorie Broadbent (June 2nd, p. 978) mention the use of sodium iodide with ephedrine in the treatment of asthma. It appears probable that the action of sodium iodide depends mainly on stimulation of thyroid activity, and that equally good results might be obtained by the administration of tab. thyroid. B.P. It has been found that thyroid feeding increases the effect of pyrogenic substances (β -tetrahydronaphthylamine, T.A.B. vaccine), while thyroidectomy diminishes the response.¹

As the effect of these substances appears to depend on their stimulation of sympathetic activity it occurred to me to test the effect of combining thyroid administration with ephedrine medication. The results obtained were definitely better than those from ephedrine alone. In one adult 1/2 grain dose of ephedrine hydrochloride twice daily gave little relief, but 1/4 grain dose at night with 1 grain of thyroid (B.P.) in the morning kept him free from attacks for some months. An attempt to reduce the thyroid to 1/2 grain produced a slight attack. Toxic effects have not been troublesome, with the exception of nocturnal excitement, which may be produced by even 1/2 grain dose in an adult.

In conclusion, I should like to mention that the best sympathetic stimulant is cold, which can generally be obtained by good ventilation and underclothing.—I am, etc.,

Bradford, June 9th.

H. S. RUSSELL, M.D.

The Ubiquitous Acid-fast Bacillus

SIR,—The following incident, which I am asked to publish, further illustrates Dr. Gregory Kayne's valuable contribution to the *Journal* of April 28th (p. 734).

During a hot, dusty khamseen day in Cairo, while M.B. examinations were in progress, I cleared my throat into a sink in my laboratory. Curious to know what one swallows in dust, I whipped up the sputum with a platinum loop on to several slides and stained these (including a Ziehl-Neelsen). The slides show an acid-fast, alcohol-fast bacillus—morphologically identical with the tubercle bacillus—in every third field. An assistant, like myself, disliked their appearance in my sputum. That I had been infected by the tubercle bacillus I was not prepared to believe! After examining all the stains, reagents, and bottles, I finally made swabs from the sink bottom to find the *fons et origo* of my anxiety. This particular sink, very little used and not properly cleaned, had a surface film of acid-fast bacilli very useful for teaching purposes.—I am, etc.,

Cairo, May 28th.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

In the House of Commons this week the committee stage of the Finance Bill was concluded. The Ministry of Health Estimates were down for June 14th to permit a discussion on slum clearance, but a debate on the Home Office Estimates was substituted. Discussion was also arranged on a report from the Committee of Privileges.

The South Devon and East Cornwall Hospital, Plymouth, Royal Albert Hospital, Devonport, and Central Hospital, Plymouth (Amalgamation, Etc.) Bill was reported to the House of Commons with amendments from a Select Committee on June 7th. This Bill has passed the House of Lords.

The Licensing (Permitted Hours) Bill passed through committee, and was read a third time in the House of Commons on June 7th.

On June 12th the Betting and Lotteries Bill and the Workmen's Compensation (Coal Mines) Bill were considered on report in the House of Lords, and the Licensing (Permitted Hours) Bill was read a second time.

Compensation to Doctors for Road Accidents

In Standing Committee, of the House of Commons, on June 7th, the following new clause to the Road Traffic Bill on the "Payment and insurance in respect of emergency treatment of injuries arising from the use of motor vehicles on the road" was considered:

(1) Where medical or surgical treatment or examination is immediately required as a result of bodily injury (including fatal injury) to any person caused by, or arising out of, the use of a motor vehicle on a road, or in a place to which the public have a right of access, and the treatment or examination so required (in this section referred to as "emergency treatment") is effected by a registered medical practitioner, the owner of the vehicle shall, on a claim being made in accordance with the provisions of the next succeeding section, pay to the practitioner, or, where emergency treatment is effected by more than one practitioner, to the practitioner by whom it is first effected:

(a) a fee of twelve shillings and sixpence in respect of each person in whose case the emergency treatment is effected by him; and

(b) a sum, in respect of any distance in excess of two miles which he must cover in order to proceed from the place whence he is summoned to the place where the emergency treatment is carried out by him and to return to the first-mentioned place, equal to sixpence for every complete mile and additional part of a mile of that distance.

(2) Where emergency treatment is carried out in a hospital (that is to say, an institution, not being an institution carried on for profit, which provides medical or surgical treatment for in-patients) the provisions of the foregoing subsection with respect to the payment of a fee shall have effect with the substitution of references to the hospital for references to a registered medical practitioner.

(3) Liability incurred under this section by the owner of a vehicle shall, where the event out of which it arose was caused by the wrongful act of another person, be treated for the purposes of any claim to recover damage by reason of that wrongful act as damage sustained by the owner.

(4) A policy of insurance or a security in respect of third-party risks shall not be deemed to comply with the requirements of Part II of the principal Act unless the owner of the vehicle to which it relates is specified therein for the purposes of paragraph (b) of subsection (1) of section thirty-six, or of section thirty-seven of the said Act, as the case may be, and, notwithstanding anything in the proviso to paragraph (b) of subsection (1) of the said section thirty-six, any liability which may be incurred under this section by the owner shall be deemed to be a liability required to be covered under that paragraph.

Debate in Committee

Mr. GUY, who, in the absence of Sir Francis Fremantle, moved that the clause be read a second time, said the purpose of the clause was to provide payments to hospitals and doctors. If one of the amendments to it were accepted payments would also be made to an ambulance association which provided emergency treatment or first aid. A formidable number of people in each year received first-aid treatment from doctors, hospitals, and ambulance associations, but in the majority of cases none of these received any payment for the

services rendered. The British Medical Association mentioned one instance of a practitioner who treated 100 cases caused by motor accidents during a year but only received payment in four of them. Last year Parliament provided for certain payments to hospitals in the Road and Rail Act, but no provision had been made for emergency treatment by doctors nor to the hospitals for first aid. The clause proposed a fee of 12s. 6d.; that was not extravagant. It had been put into two Bills which passed through the House of Lords recently, one of which incorporated the whole of the two clauses Mr. GUY now proposed to add to the Road Traffic Bill. The proposal had received consideration in responsible quarters, and had considerable backing throughout the country. If the clause were adopted, and a pedestrian were injured in a motor accident and received first-aid treatment at a doctor's house, the owner of the motor car involved in the accident would have to pay the sum of 12s. 6d. to the doctor concerned. In the provision made in the Road and Rail Act in respect of hospitals these payments were conditional on the admission of negligence on the part of the motorist. In the present proposals the payment was to be irrespective of negligence. The total cost would be in the neighbourhood of £250,000 yearly, probably less. If the motorist were covered by his insurance company something like 2s. 6d. would be added to the premium.

A later clause provided that a claim might be made at the time of treatment, and that if the payment was made the question would be ended. Failing that, a claim should be made in writing within seven days.

Sir E. GRAHAM-LITTLE supported the clause. He said the King Edward's Hospital Fund for London and the British Hospitals Association urged the adoption of a clause which was to follow the one now under discussion. Mr. STANLEY, the Minister in charge of the Bill, said the second clause had nothing to do with emergency treatment, but allowed the hospital to recover up to £50 for any person injured in a road accident.

Sir P. SANDERSON said it was vital that the responsibility of insurance should not be passed on to the owner of the car instead of on the user as the present clause would do. Mr. STANLEY agreed with Sir Frank Sanderson that it would be necessary to make an amendment in this sense. The Act of 1930, he said, did not put an onus on any man as the owner of a car but as the potential user. He (Mr. Stanley) could not accept anything which would create a breach of that principle. There was no liability on the man who owned a car to insure. Everybody recognized the great hardships caused to doctors by the additional calls through road accidents and the difficulty they had in getting payment for their work. The Standing Committee would like to do what was possible to help the doctors, but the principle of law which the amendment would alter was a very large one. It was the principle that a man was liable only for his own negligence. Under the new clause the motorist would be liable whether at fault or not. He might prove that all the blame for the accident rested upon the cyclist or the pedestrian, but that would be no defence. Mr. GUY had argued that the clause would not imply any hardship on the motorist, but he had not disclosed to the committee that there were in his name two other amendments which would extend this principle. He confessed it was a shock to him to see the new clause which had been put down in respect of hospitals. He should resist to the utmost these further extensions of the principle. The committee might well feel that the grievance of the doctors was so substantial, and the proposed burden on the motorist so light, that the clause should be passed, but the committee would only be safe in doing so if at the same time it determined it would not allow this breach of principle to be further and further widened. He was not opposing the clause as it had been moved; in this case he himself was prepared to overlook the breach of principle.

Mr. STOREY said if the burden was not to be put upon the motorist it would fall upon the doctor and the hospital, and there was no more reason why they should have to bear it than the motorist who was not negligent. The latest figures from the King's Fund showed that the cost of attendance on motorists, which was not recovered at present, was about £180,000. If that were distributed over all the motor licences in the country it would only take 1s. 7d. per head to cover

it. That figure showed that the second clause put down would not extend very far the principle to which Mr. Stanley took exception. In practice the cost of the compensation to hospitals to be proposed in the second clause would not amount to £180,000, because all cost of treatment over £50 would be ruled out from recovery, and he knew of cases where the cost had run up to £165. Sir GIFFORD FOX said the committee hoped the Bill would reduce the number of accidents, and it might perhaps follow that the insurance companies might not require to increase premiums. Sir WILLIAM BRASS complained that pedal cyclists were not to be affected by this clause, nor were tramways, although over 1,000 pedal cyclists were responsible for fatal accidents during the year.

Major HARVEY said he was president of more than one hospital, and had every sympathy with doctors and hospitals, but he failed to see why the motoring public should pay extra to insurance companies to pay the doctors' expenses for accidents which were not the motorists' fault. Mr. D. GRENFELL also opposed the clause, and said he would be glad to see a device for compensation to doctors from the Road Fund. Major LLOYD GEORGE said he did not agree that there might be a danger of doctors not attending accidents if they were not paid. No other profession in the world did so much for nothing. That made it all the more incumbent on the committee to find some scheme by which the doctors could be sure of payment. Mr. TURTON said the new clause by itself would have little financial effect in doctors' accounts, and would promote hostility. He thought the cost of the driving licence should be increased from 5s. to 7s., and the increase should be devoted to the hospitals. That was a contribution which the motorist would be glad to pay. In Mr. Turton's opinion the grievance of the doctors was nothing like that which was suffered by the hospitals on the main arteries of traffic.

Mr. STANLEY said that he objected to the clause failing any assurance by the promoters that if he accepted it they would not press either the amendment or a new clause. Mr. GUY agreed that the new clause dealing with hospitals would make a much more substantial change. In many cases, where first-aid or emergency treatment was rendered, and where negligence was established or was admitted by the motorist, the doctor or the hospital had not received a penny. The new clause would enable the doctor to recover payment in a considerable number of cases where under the existing law of negligence he would be able to recover damages.

On a division, fourteen votes were cast for the clause and nine against it; the clause was read a second time and added to the Bill.

The Standing Committee of the House of Commons gave further consideration, on June 12th, to the Road Traffic Bill.

Sir W. BRASS moved an amendment to make the new clause applicable to all kinds of vehicles. Mr. GUY said that the promoters of the clause would not resist the amendment. Mr. STANLEY expressed surprise at this decision. The clause, he said, was inextricably bound up with compulsory insurance under the Act of 1930, and it was fantasy to bring under the clause persons who were not compulsorily insured.

The amendment was negatived by 22 votes to 8.

Mr. STANLEY moved an amendment providing that liability for payment for emergency treatment should be placed on the user of the motor vehicle at the time that the accident occurred. Doctors and hospitals would not suffer in any way by confining the claim to the person using the vehicle at the time of the accident.

The amendment was agreed to.

Colonel CROOKSHANK moved an amendment providing that a voluntary ambulance association should be entitled to claim a fee of 10s. in respect of each person transported. Mr. STANLEY said that an ambulance association which performed voluntary work was in a different position from medical men and hospitals. The services which ambulance associations rendered were limited by the funds which they had at their disposal, and if they got more money they could extend their activities. Hospitals, on the other hand, had to maintain certain general services, and if they gave emergency treatment that might involve them in heavy liability. Doctors in many cases received no remuneration for the services which they rendered. Sir F. FREMANTLE supported the amendment,

and thought it was not at variance with the principle of the clause.

The amendment was negatived by 29 votes to 9 and the clause as amended added to the Bill by 28 votes to 7.

Sir E. FREMANTLE moved a new clause providing machinery for the recovery of claims on the part of doctors and hospitals. The clause was read a second time and added to the Bill.

The committee adjourned before reaching the proposed new clause dealing with payments to hospitals for treatment of road casualty cases, to which reference had been made in the discussion.

Compensation to the Injured Party in Road Accidents

Lord DANESFORT, in the House of Lords on June 7th, moved the second reading of the Road Traffic (Compensation for Accidents) Bill. He said its object was to secure in proper cases adequate compensation for pedestrians, pedal cyclists, and other non-motoring persons who were killed and injured on the roads. Under the existing law the compensation was entirely inadequate. The principle of the Bill was that the injured party was not bound to prove negligence on the part of the motorist before launching his claim. When a similar Bill was introduced in June, 1932, the Lord Chancellor had said: "This is not a new principle, but a principle which has been in our law for generations, and it does not seem to be a very alarming or revolutionary change to apply it to a potentially dangerous machine like a motor vehicle." Lord Danesfort recapitulated the progress made on the Bill of 1932, and on a similar one in 1933, which had been referred to a select committee with Lord Iveagh as chairman. The hospital clause contained in the latter was so favourably viewed by the Government that it was inserted in one of the Government's own Bills, which was passed. That was why this clause was omitted from the present Bill. Lord LAMINGTON supported the Bill, and commended the principle introduced in the Irish Free State by which the insurer in cases of road traffic accidents was only paid money when he had compensated the person injured. Lord HOWE opposed it. After further discussion it was read a second time by 19 votes to 4, and referred to a committee of the whole house.

Duty on Arc-Lamp Carbons

In the House of Commons on June 4th, in committee on the Finance Bill, a debate arose on Clause 4 (increase of customs duty on arc-lamp carbons). Mr. DAVID GRENFELL moved an amendment to reduce the duty on arc-lamp carbons of more than 14 millimetres in diameter from 5s. to 1s. 6d. per lb. He said that in hospitals and clinics the lighting, which had become a general feature of medical therapeutics, was done by these arc lamps. The duty, which under the Bill was raised to 5s., was onerous. Sir P. HARRIS, in supporting the amendment, said in the treatment of skin diseases electricity was of benefit, and the electric carbon had been an effective contribution to medical science and the work of hospitals. The consulting engineer of St. Bartholomew's Hospital had told him that he had made long and laborious experiments in carbons, and had found that the imported article was the only carbon which could be relied on to give perfect treatment, without risk or danger to the patient, and to the satisfaction of the doctor.

Dr. BURGIN said that an analysis of the quantity of carbons consumed in this country in a normal year showed that the consumption of hospitals was something under 2 per cent. Fully 85 per cent. was used by the cinematograph industry. The duty was put on at the joint request of the makers of the article and the consumers of 85 per cent. of it. The case for the duty was clearly made out, all the normal safeguards to see that interests were not affected had been obtained, and undertakings were given by manufacturers that prices would be reduced. Sir ARCHIBALD SINCLAIR said Dr. Burgin had made a great point that the hospitals had not gone to the Board of Trade to make representations, but the hospitals would be reluctant to mix themselves up in a matter which had become one of political controversy in the House of Commons. As their interest in it was only 2 per cent. the hospitals might well have thought that it was not a matter in which they would care to join in opposing the duty. But that did not alter the fact that the

duty would, to some extent, raise the cost of light therapy in this country.

The amendment was negatived by 243 votes to 45.

On the motion that the clause should stand part of the Bill, Dr. Burgin explained that the object of the duty was to encourage the manufacture in this country of an article, the raw material of which was lamp-black, of which there was an adequate supply. It would be made free of foreign control, and the duty was granted under conditions by which the consumer was protected. The clause was carried by 247 votes to 45.

Water Supplies

In reply to Mr. Bernays, on June 7th, Mr. SHAKESPEARE said the position regarding water supplies in the North and East, Wales, and in the West, as well as in part of the Midlands, was generally better than it was a month ago. The South and South-East had not shared in the improvement. He had no reason to think that water undertakers would not be able to meet the situation, provided consumers played their part by reasonable economy in the use of water. Such co-operation so far accounted largely for improved conditions. In rural areas with defective supplies the authorities should expedite methods for permanent schemes with the grant available under the Rural Water Supplies Act.

Sir HILTON YOUNG told Mr. Joel, on June 7th, that he was not aware of any empty or relatively empty reservoirs in the country, though in some areas reserves were seriously low. Active steps had been taken in these areas to conserve supplies, with the co-operation of consumers, and to augment them. Further powers could be obtained expeditiously under the Water Supplies (Exceptional Shortage Orders) Act recently passed.

Children's Allowances and Cost of Minimum Diet

The House of Lords, on June 6th and 7th, discussed the Unemployment Bill on the motion for second reading. Lord MARLEY opposed the Bill, and said that when a Labour Government came in it would be repealed. The low benefits to be paid meant nothing else but insufficient food. The means test had been maintained with inadequate children's allowances. Under the means test there was left to a family to expend on rent and food a sum which experience had shown was quite inadequate. The British Medical Association appointed a committee on nutrition, which reported that for a child of 1 to 2 years the minimum sum necessary was 2s. 8d., for a child from 3 to 6 years 3s. 4½d., and for a child from 8 to 10 years 4s. 2d. The Bill allowed 2s. Even if a child were given one pint of milk a day and nothing else that would come to 1s. 8d. a week. What was left of the 2s. when they had given the pint a day? The report stated that one pint of milk a day from the age of 1 to 5 years, and half a pint a day to 10 years, constituted a sufficient and safe quantity, but more could be given with advantage. The committee of the British Medical Association said that during the compilation of these diets constant vigilance had been exercised to keep the cost down to the minimum which permitted the purchase of an adequate diet. It had not been possible to prepare a diet for a child alone at a less cost than 2s. 6d. a week. The present head of the medical service of the London County Council, Mr. Somerville Hastings, gave, in an article in the *Lancet* about a year ago, a report of an examination which he undertook of twenty-one unemployed families on the means test. Fifty-three children were examined, and thirty-three were found to be undernourished. The sum available for food, warmth, and clothing in these families varied from 1s. 4d. to 4s. 6d. a head, and averaged 2s. 5½d. per family. In Merthyr, where about 90 per cent. of the miners were unemployed, the infantile mortality rate was 73 per 1,000, compared with 65 per 1,000 in the rest of the country. That was 8 per cent. higher because the children had not enough food to live on. The rate had, it was true, been reduced in the last two years from 129 to 73 per 1,000, but the medical officer of health, in making the report, gave a warning that while the drop was gratifying it was too early yet to attribute very great significance to it. He

maintained that insufficient food for the people was the cause of the higher death rate of children under 1 year. This was having an effect on tuberculosis. The Committee on Malnutrition found that in the three years 1925 to 1927 the death rate from consumption in the depressed areas was 61 per million greater than in the more fortunate areas. Since unemployment had become much worse, the figure had risen to 95 per million.

Lord ELTON referred to statistics published last September by the Chief Medical Officer of Health, Sir George Newman, which showed that during 1932, in the period of the deepest depression, the two most characteristic tests of malnutrition—infantile mortality and deaths from tuberculosis—had not only decreased, but were the lowest on record. The Chief Medical Officer compared the figures in two groups of industrial areas, one with a heavy and the other a light incidence of unemployment, and arrived at the result that not only were the mortality and other rates in the bad area not inferior to those in the good area, but, on the average, the improvement in the area where the incidence of unemployment was heavy was actually greater than in the area where it was light. Lord Elton said he did not suggest that that was typical, but at any rate it gave grounds for optimism, and a Bill which so conspicuously increased the generosity with which benefit rates were administered was not the best occasion for Lord Marley to treat them to a speech 75 per cent. of which was a description of the awful results of malnutrition, which undoubtedly existed, which had existed under all Governments, and which they hoped this Bill was likely to decrease.

The Bill was read a second time without a division.

Milk Bill: Second Reading

The Milk Bill introduced by Dr. Elliot came before the House of Commons for second reading on June 7th. Dr. ELLIOT said the Opposition had placed an amendment on the paper taking exception to the rate at which the Government was proceeding in the campaign for cleaning up the herds. The proposals of the Government of Northern Ireland went much further than those which had been laid before the House of Commons. In Northern Ireland the sale of liquid milk for consumption below Grade C was prohibited. Even on the Grade C milk a levy running as high as 3½d. a gallon was provided for, to be used to assist the better qualities of milk, and the cows would be inspected twice a year. These drastic proposals went far beyond what the United Kingdom Government could introduce immediately in this country. Clause 6 of the Bill provided for Exchequer payments to the Government of Northern Ireland to be used for assisting milk producers in that country. Explaining other clauses of the Bill, Dr. Elliot said the present danger was that a still lower level of prices in the milk industry would lead to a diminution in the supply of home-produced milk. The Bill enabled the Minister to spend up to £750,000 during four years in such a way as he thought would improve the quality of milk for human consumption. It would amend Section 3 of the Milk and Dairies Amendment Act, 1922, to enable the Minister to revise the designations of milk. It contained provision for increasing the demand for milk, but did not refer specifically to milk in schools. The assurance he gave on February 22nd that the programmes of milk marketing boards would be required to contain provisions for the supply of milk to schools at reduced rates still stood; he did not think it necessary to incorporate a clause in the Bill. He was assured by his technical advisers that the Government was proceeding as rapidly as was reasonable towards the eradication of disease from herds. The Cattle Diseases Committee suggested that large municipalities should have the right to require that after two years all milk, except sterilized milk, sold within their boundaries, and not derived from tuberculosis-free herds, should be pasteurized, but that the power to exercise that right should be deferred for three years. Five years would elapse before the committee considered it was possible to arrange for any large supply of tuberculosis-free cattle. The Government programme provided for the payment of premiums to attested herds. That should bring perhaps a thousand herds in the first year. A general

campaign of slaughter and killing of affected cows in this country was not possible because of the lack of milk that would ensue.

AMENDMENT FOR REJECTION

Sir STAFFORD CRIPPS, for the Labour Opposition, moved a reasoned amendment to reject the Bill on the grounds that it sought to encourage the output of milk products in preference to increasing consumption of fresh milk by children in public elementary schools, and that it failed to make adequate provision for the eradication of disease from cattle. He quoted a declaration made by Lord Moyrihan at the Mansion House nearly two years ago that the drinking of contaminated milk caused a large proportion of surgical tuberculosis and some medical tuberculosis. The lack of inspection of herds under the existing inspectorate in county areas called for far more drastic action than Dr. Elliot proposed to take. The Labour Opposition believed the Minister should take powers similar to those he had for dealing with foot-and-mouth disease—the right to condemn and the right to isolate, with administration through a central inspectorate under the Livestock Department of the Board of Agriculture. It was unnecessary to wait until all the herds in the country were cleaned up before considering the wider distribution of liquid milk. By other means the milk could be made safe for children. If 90,000,000 gallons annually were taken for distribution to children that would create a habit for liquid milk, and the supply could be financed at no greater cost than was proposed in Dr. Elliot's scheme.

Sir FRANCIS ACLAND said that to clean up the herds by eliminating reactors to the tuberculin test would be slow and uncertain. He doubted if by that process half the herds would be clean in twenty-five years. Immunization by inoculation would be speedier and more effective, and he thought the country was near to it. If those responsible would consult Dr. Nathan Raw and Dr. W. M. Crofton, and would conduct experiments with proper scientific controls, they would quickly discover methods of building up herds immune from subsequent infection. The inoculation must be applied to newborn calves. Mrs. WARD said there was no alternative to cleaning the herds. One could not be certain in buying pasteurized milk that it was free from tubercle bacilli. Doctors were much divided in opinion on this subject. If cattle were tested with tuberculin two months passed before the final result of the test was available. In six months, if the cattle were again tested, some which had been found free from tubercle would react as a result of the irritation set up by the previous injection. Mr. RICHARD RUSSELL said there was no tuberculous milk unless there was a tuberculous condition of the udder, and that was not found in more than 5 per cent. of cows. Pasteurized milk alone would starve a child. It had to be supplemented by cod-liver oil or by citrus fruit. The only way to safeguard the supply was to clean up the herds by dealing with the rising generation of cattle. Calves should be taken away from any possible source of contamination.

Sir ERNEST GRAHAM-LITTLE said the cleaning up of herds could not be applied against every disease derived from milk. It had been applied practically only to tuberculosis. The method was expensive, the results, to a certain degree, satisfactory. Samples of certified milk showed an incidence of about 2 per cent. in milk supposed to be free from tubercle—a relatively small incidence—but no freedom was secured by that method from other diseases of milk, which were becoming more frequent and more widely recognized. Milk tanks were almost uniformly infected with tubercle before pasteurization, as was proved in tests supervised by officers of the laboratory of the Royal Veterinary College. Treatment by heat destroyed the bacilli of tubercle, of the *Brucella abortus*, and of septic sore throat. To say pasteurization destroyed the value of milk was fallacious. Medical authorities were agreed that in pasteurization they had an economical method of rendering milk safe and clean. It had become the opinion of the medical profession that to distribute milk of any kind in the raw state, even tuberculin-tested milk, was unwise. Sir Ernest added that he believed an immediate distribution of milk would improve the nutrition of the children, and that at relatively small expense safety could be secured from any disease infecting the milk. He denied that pasteurization encouraged uncleanness in the distributors of milk.

Mr. DREWE said many farmers, when they had cows tested, put the reactors on the market, and so freed their own herds. He asked if the Minister could arrange to give greater compensation if the farmers slaughtered the cows which, in the opinion of a veterinary surgeon, ought not to go on the market. Mr. TOM WILLIAMS said medical associations like the Royal Society of Medicine and the Royal College of Surgeons were satisfied as to the nutritive value of fresh milk, and desired to recommend greater consumption, but were afraid to do so because they knew that the milk supply in this country was not so pure as it ought to be.

Mr. SKELTON, replying for the Government, said that calculations of the cost of supplying milk to school children must allow for most careful handling of the milk from the time it left the farm until it was presented to each child in a sealed bottle. That could not be done for 3d. a gallon. The Government, while developing the supply of milk for school children, also kept in mind that milk was the raw material for industries which it would not allow to be destroyed. In the cleaning up of the herds the Government already had powers of slaughter, but believed that to encourage the cleaning up it must make it worth while.

The second reading was carried by 190 to 47.

Reduced Telephone Charges to Doctors

Introducing the Post Office Estimates in the House of Commons on June 6th, Sir KINGSLEY WOOD announced reductions in telephone charges, and said he proposed to introduce a new business rate for doctors, district nurses, and others to whom the telephone was mainly a means of communication from outside callers, these subscribers originating few calls themselves. For these a fresh form of tariff was proposed, intermediate between the two main business and residential tariffs. It would be called the "Small User Business Rate." The rental per quarter in the provinces would be £1 6s., in the four large cities £1 9s., and in London £1 12s. These subscribers would be subject to an increased charge of 50 per cent. on the first forty-eight call units a month. Their total bill would never be more than that of the ordinary business user, and for limited use it would be appreciably less.

On June 11th Sir ROBERT HAMILTON asked what the rental charges would be under the proposed new scale for a doctor's telephone in a country district in Shetland, now charged at £12 per annum. Sir KINGSLEY WOOD said he understood Sir Robert to refer to a subscriber who did not come within the ordinary tariff conditions, but paid a specially assessed rental. Whether any rental reduction could be made in such cases was under consideration.

Atmosphere of the House of Commons.—On June 5th Mr. ORMSBY-GORE told Mr. Bernays that he had recently had analyses made of the air in the chamber and lobbies of the House of Commons at different times of the day. He was further carrying out a similar but more complete survey of the ventilation of the whole building, as a result of which he hoped it might be possible for more definite conclusions to be reached. His personal impression that the air was unsatisfactory had not been confirmed by the scientific and technical experts who had investigated the matter. Sir WILLIAM DAVISON asked if Mr. Ormsby-Gore was aware of the practice which obtained some years ago in the House of providing streptococci with bowls of broth from time to time in order to test their numbers and strength, and if any recent provision had recently been made for similar trials. No reply was given to this question.

Blood Test in Drunkenness.—In reply to Mr. Hales, on June 7th, Sir JOHN GILMOUR said evidence from a blood test was sometimes given in this country where drunkenness was an element in a criminal charge, but he had no power to require any person to submit to such a test.

Opponents of Vaccination.—Sir HILTON YOUNG told Mr. Grouse, on June 6th, that he had seen the resolution passed at the annual meeting of the National Anti-Vaccination League. He would consider receiving a deputation from the opponents of vaccination before introducing legislation on the subject.

Universities and Colleges

UNIVERSITY OF OXFORD

The following have been elected to the Board of the Faculty of Medicine by the General Medical Electorate: C. F. T. East, D.M., and C.P. Symonds, D.M., New College.

UNIVERSITY OF CAMBRIDGE

The Vice-Chancellor gives notice that a congregation will be held on Saturday, August 4th, at 2 p.m. No degrees will be conferred at this congregation except upon persons qualified to proceed then to medical or surgical degrees.

The Faculty Board of Medicine has appointed Dr. G. Harrison Orton a member of the Committee for Medical Radiology and Electrology until December 31st, 1934, in the room of the late Dr. Stanley Melville.

At a congregation on June 8th a Grace was approved for conferment of the degree of Master of Arts, *honoris causa*, upon Sir Charles James Martin, C.M.G., D.Sc., F.R.C.P., F.R.S., who is now resident at Cambridge and engaged in research there. The degree was conferred that day.

The title of the degree of M.D. has been conferred by diploma on Mrs. A. G. Dauncey of Newnham College.

At the congregation on June 8th the following medical degrees were conferred:

M.B., B.Chir.—H. T. Cox, W. R. Billington, R. V. Payne, H. D. White, W. Wilson, J. L. Parker.
B.Chir.—E. J. Neill, W. E. Tucker.

*By proxy.

UNIVERSITY OF LONDON

The University Court on June 6th was informed that the Kent County Council, acting on the recommendation of its Education Committee, had decided to make a grant of £40,000, payable over ten years, towards the cost of erecting new University buildings on the Bloomsbury site. The Court has conveyed most cordial thanks to the Kent County Council and Education Committee for this munificent gift.

The following candidates have been approved at the examination indicated:

Turn M.B., B.S.—†R. H. R. Belsey, *†E. W. Binteliffe, *†Edith J. R. Browne (University Medal), *†A. M. R. Cann, *†D. R. Davies, *†R. R. Henderson, *†L. G. Jones, *†L. E. Jones, *†Beryl Twyman, *†Sylvia V. F. Wolfe, Mary A. C. Adams, J. L. Bates, Mary A. M. Bigby, Eileen A. Chennell, J. A. Chivers, J. G. R. Clarke, Doris Cohen, Beryl D. Cnrner, C. F. Critchley, E. A. Danino, D. M. Dean, C. B. Dharinasena, I. Doniach, O. G. Edholm, R. T. Elven, Nancie I. Faux, Constance E. Field, J. M. Flower, H. E. D. Gale, C. J. Gavey, N. Green, J. T. Griffiths, Hilary Ginton, R. M. Haines, S. T. Hayward, Alice M. Head, G. F. Henderson, E. F. Hewlitt, A. C. Howard, H. C. Hugh, N. M. Jacoby, Elizabeth M. James, Margaret H. James, H. W. E. Jones, W. S. G. Lawson, H. B. Lee, Rosamund M. I. Mackay, G. A. Mals, S. P. Mason, P. H. Nankivell, Doris E. Oxlford, H. Royle, G. C. Sawyer, Margaret H. Scott, C. Seeley, H. L. Selwyn, R. Shackman, J. V. Shemilt, D. G. Snell, W. P. Stamm, J. P. Stamford, Mary G. Tate, W. P. McK. Teller, T. P. J. McQ. Thomas, A. S. Thorley, W. W. Elizabeth B. White.

The following candidates have passed in one of the two groups of subjects:

Group I.—S. H. Alavi, G. W. Bender, D. M. Blomfield, J. A. Brocklebank, I. A. Cathie, Enid S. Davies, Audrey P. Dence, D. G. ff. Edward, Evelyn J. Forgan, W. T. J. Fowler, Joan I. Franklin-Adams, D. B. Hyslop, A. D. Hild, F. A. Jones, Margaret M. C. Loudon, J. I. Maran, G. D. Morgan, Barbara G. Morton, F. E. Norris, D. S. Piper, Irene E. Sandford, K. G. Seager, H. W. G. Staunton, D. L. McK. Stewart, H. A. Thomas, Sarah C. B. Walker, M. F. Wigfield.

Group II.—H. H. Atkinson, E. A. Bisson, Muriel Boycott, D. J. T. Brinkworth, R. Bruce, R. Carpenter, R. F. Clarke, C. W. J. Claydon, D. W. A. Deacon, Lynette Dowsett, H. D. C. Fairman, E. D. Falconer, T. F. R. Griffin, A. W. I. Houghton, Joyce B. Jewson, W. L. Kerr, G. A. Kiloh, J. R. Kingdon, K. A. Latter, S. Lee, C. F. Mayo-Smith, R. H. Purnell, D. C. Reavell, J. D. Richardson, A. T. Roden, Catherine L. Simmons, B. W. Smith, M. C. L. Smith, E. J. Somerset, W. H. C. Spooner, K. P. Stephens, Margaret E. Sutherland, R. E. Thomas, W. F. Townsend-Coles, R. J. Vakil, E. C. Zorab.

* Honours † Distinguished in Medicine. ‡ Distinguished in Pathology. § Distinguished in Surgery. ¶ Distinguished in Obstetrics and Gynaecology.

UNIVERSITY OF SHEFFIELD

At a meeting of the University Council on June 11th Dr. Edward Mellanby, F.R.S., late Professor of Pharmacology in the University, and now Secretary of the Medical Research Council, was appointed Emeritus Professor.

Obituary

Dr. AGNES BRYCE SMITH, who died last month in the Royal Isle of Wight County Hospital, received her medical education at King's College Hospital, London, whence she graduated M.B., B.S.Lond. in 1923, and obtained the diplomas M.R.C.S., L.R.C.P. in the same year. After holding the post of house-physician to the hospital, she was appointed house-surgeon to the Royal Isle of Wight County Hospital at Ryde. After two years of institutional work she started private practice in Ryde, and was then the only woman medical practitioner in the island. A short time afterwards she was appointed visiting anaesthetist to the County Hospital. Her practice developed steadily, and she gained the friendship and respect of her brother practitioners in the island. Two years ago she had to cease work owing to the onset of a long and trying illness, and death ensued at the early age of 35. She was the only daughter of the late Dr. A. S. Smith of Chagford, Devon, and her brother is also in the medical profession.

We regret to record the death of Dr. EDWARD BERESFORD COLLINGS at Barnsley on June 2nd, at the age of 71. He was born in 1863, and, after studying at the Leeds School of Medicine, obtained the M.R.C.S. and L.R.C.P. diplomas in 1891. He went to Barnsley from Bath in 1893, in partnership with his brother-in-law, the late Dr. White, and for forty years had been medical officer to the Poor Law Infirmary. Dr. Collings was an enthusiastic swimmer, and taught the art to many children. His proficiency in that particular sport was responsible for the saving of two lives in December, 1915, when, while on the way to visit a patient, he found that a woman who could not swim had jumped into the canal to the rescue of her 12-year-old son. Dr. Collings plunged in, and brought mother and son to the bank. He had been a member of the British Medical Association since 1907, and during the war served in France as a temporary captain in the R.A.M.C.

Medical News

The eighth annual Macalister Lecture will be delivered by Dr. Robert Hutchison on "Praise and Dispraise of Doctors" at the National Temperance Hospital, Hampstead Road, N.W., on Thursday, June 21st, at 9 p.m. All medical practitioners and their friends are invited.

On Wednesday, June 27th, at 5 p.m., at the house of the Royal Society of Medicine, 1, Wimpole Street, W., Dr. William Allen Pusey of Chicago will deliver the Prosser White Oration on "Disease, Godly of the Mind, Especially the Stimulus of Disease in the Development of the Mind," before the St. John's Hospital Dermatological Society.

A meeting of the Eugenics Society will be held at the Linnean Society's Rooms, Burlington House, Piccadilly, W., on Tuesday, June 26th, at 5.15 p.m., when Professor F. A. E. Crew will speak on "The Inheritance of Educability in the Rat." Sir Humphry Rolleston will take the chair.

The annual meeting of the Incorporated Lancashire and Cheshire Society for the Permanent Care of the Feeble-minded will be held at the Mary Dendy Homes, Sandbridge, on June 19th, at 2.30 p.m., with the Lord Mayor of Manchester in the chair. The Ashby Memorial Hospital, the farm and gardens, and the new homes will be open for inspection after the meeting; tea at Warford Hall.

The annual dinner of the West London Medico-Chirurgical Society will be held at the Trocadero Restaurant, W., on Wednesday, July 4th, at 8 p.m. The annual general meeting of the society will be held at West London Hospital on Friday, July 6th, at 5 p.m.

A tabular statement of post-graduate courses and lectures to be given in London during June and July appeared in last week's *Supplement* (p. 269). The programme drawn up by the Fellowship of Medicine (1, Wimpole Street, W.) includes lecture-demonstrations at 11, Chandos Street, W., June 19th and 26th, at 2.30 p.m.; a fortnight's course in children's diseases at the Children's Clinic, June 25th to July 7th; and another in cardiology at the National Heart Hospital during the same period; a course in medicine and surgery at the Metropolitan Hospital, June 30th and July 1st; and a course in ophthalmology at the Central London Ophthalmic Hospital, July 2nd to July 7th.

At the meeting of the National Smoke Abatement Society, held in Caxton Hall, Westminster, on June 8th, Dr. H. A. Des Vœux said that it was in this hall that he had originally put forward his idea of a campaign for the prevention of the smoke nuisance. The various papers read at the meeting were concerned chiefly with the control of domestic smoke by the use of smokeless fuels and gas coke in the open-grate fire. Among those present were the two representatives of the British Medical Association—Mr. Bishop Harman and Dr. Clark Trotter.

The Royal Sanitary Institute (90, Buckingham Palace Road, S.W.) announces that the health exhibition to be held in connexion with the forty-fifth congress of the institute will be accommodated in the Colston Hall, Bristol, from July 9th to 14th.

The fourth conference of the International Association of Preventive Paediatrics (medical section of the Save the Children International Union) will be held this year at Lyons on September 27th and 28th. The subjects to be discussed and the names of the rapporteurs are: (1) "Prophylaxis of Malaria in Children"—Professors Cacace (Naples) and Gillot (Algiers), with whom will be associated Dr. Larrouy (a British rapporteur will be named later); (2) "Prophylaxis of Rickets and Convulsions"—Professors Adam (Danzig) and Monrad (Copenhagen). Those who desire to be present at the conference, as well as to take part in the discussions following on the reports, are requested to communicate with the secretary of the I.A.P.P., 15, Rue Lévrier, Geneva, Switzerland.

A congress of the International Society of Geographical Pathology (which was founded in 1927 by Askanazy, supported by Aschoff) will be held at Utrecht from July 26th to 28th. The subjects for discussion are cirrhosis of the liver, arteriosclerosis, and the organization of the society.

The fourth congress of the International Office of Documentation for Military Medicine will be held at Liège from June 28th to 30th, when the following subjects will be discussed: medical aspects of aviation, organization of the sanitary service at the base, critical study of the international registration of wounds and diseases in the war of movement, immunization against infection of wounds, disimpregnation of the linen and clothing of the gassed, bacteriological warfare, processes of disinfection, and interchange of sanitary formations during a campaign. Further information can be obtained from the director of the International Office, Lieut.-Colonel Voncken, Hôpital Militaire, Liège.

The seventh congress of the French Paediatric Association will be held in Paris from July 9th to 11th under the presidency of Professor Ombredanne, when the following subjects will be discussed: pathology of Meckel's diverticulum; the influence of climatological and meteorological conditions; and tuberculous filtrable viruses in infantile pathology.

The issue of the *Schweizerische medizinische Wochenschrift* for May 12th is dedicated to Professor F. R. Nager, who founded the university oto-rhino-laryngological clinic at Zürich in 1909.

The issue of *Paris Medical* for June 2nd is devoted to infectious diseases.

The Institute of Medical Psychology (the "Tavistock Clinic"), Malet Place, W.C.1, has received an anonymous donation of £300 "to start research work on the remedial

treatment of children who suffer nervous troubles as an after-effect of assault." Investigation of this particular problem will be begun immediately.

The centenary of the Royal Society of Medicine of Ghent was celebrated on May 27th and 28th, under the presidency of the gynaecologist Dr. van Cauwenbergh.

The Secretary of State for Scotland has appointed Dr. W. N. J. Chapman to be a Deputy Commissioner of the General Board of Control for Scotland in the room of Dr. H. F. Watson, resigned.

Dr. Fanny Halpern, assistant in psychiatry at the Vienna University, has been appointed professor of psychiatry at Shanghai University.

Professors Danielopolu of Bucarest and Bensis of Athens have been elected foreign corresponding members of the Académie de Médecine.

Professor Egon Pribram of Frankfurt has been elected a corresponding member of the Paris Society of Surgery.

The following appointments have recently been made in the German faculties of medicine: Dr. Heinrich Eymmer of Heidelberg, professor of obstetrics and gynaecology at Munich in succession to Professor A. Döderlein, Dr. Helmuth Bohnenkamp of Giessen, professor of internal medicine at Freiburg i.B., and Dr. Martin Schubert of Nanburg, professor of dermatology at Frankfurt.

The Italian Central Institute of Statistics, in the last census of April 21st, 1931, reported that the number of Italian citizens over 80 years of age was 10,522, of whom 4,420 were males and 6,102 females.

The number of cases of small-pox notified weekly in the United States has shown no appreciable change since the beginning of the year, the average number being 150. The disease is of the mild type, and no fatal cases have occurred.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the journal, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, *Amalgam* Western, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER

(Advertisements, etc.), *Amalgam* Western, London.

MEDICAL SECRETARY, *Medicine* Western, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (Telegrams: *British, Dublin*; telephone: C230 Dublin, and of the Scottish Office, 7, Drumshagh Gardens, Edinburgh (Telegrams: *Amalgam, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Fructus with Jaundice

"P. J. M." writes: I have a patient with jaundice (apparently intrahepatic in type) who suffers from almost intolerable itching. The condition in general is improving, but the itching still remains. Local applications are of value only for a comparatively short time. Injections of insulin and auto-haemotherapy have had no effect. I would be very grateful if any of your readers could suggest some other methods of relieving this very annoying symptom.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, JUNE 23rd, 1934

MUSINGS IN THE GARDEN

FIFTY YEARS' ASSOCIATION WITH THE TUBERCLE BACILLUS*

BY

SIR ROBERT PHILIP, M.A., M.D., LL.D., F.R.C.P.

EDINBURGH

It has fallen to my lot to enjoy the pleasures of fifty years' relationship with the tubercle bacillus. As an undergraduate I was reared in the pre-bacillary school, on the pathological doctrines of Virchow and his disciples, as expounded by D. J. Hamilton, and the clinical teaching of Williams, Wilson Fox, and Niemeyer. My graduation coincided with the announcement of the discovery of the tubercle bacillus. No need here to dwell on the completeness of the proof and the perfection of the demonstration—the enigma of the ages unfolded in eighteen pages, and tuberculosis relegated definitely to the group of infectious diseases.

As it chanced I came into close touch with the subject while working on the Continent (1882-3). I had my first glimpse of the bacillus in the embryological laboratory in Vienna, where I happened to be working on the development of the trachea. The beauty of the demonstration and the collateral facts awakened my interest beyond recall. That interest has remained unbroken throughout the years, and is to-day no less keen than at the beginning.

Call of the Bacillus

The more one thought of the subject the more obvious it became that tuberculosis as a disease due to infection by a definite organism had to be combated broadly on lines similar to those which had been successfully adopted in the case of other infections. This meant the opening up of a fresh field with wide possibilities. Embryology, gynaecology, and other specialties which had drawn one to Vienna got the go-by. The return to Edinburgh was less encouraging. Little was accepted as tuberculosis apart from the obvious case of advanced "consumption" or "phthisis." Everybody knew everything that was to be known about tuberculosis. If we were to get a move on, the first necessity seemed to be the establishment of a centre for the collection, grouping, and observation of cases at different stages of disease. It was not easy to get the idea understood. The need for such a centre was not admitted, nor were existing medical institutions willing to co-operate. There was a good deal of active and passive opposition.

It became clear that a new type of institution had to be erected to meet the objects in view. Hence the establishment, in 1887, of the Tuberculosis Dispensary as a centre of diagnosis, observation, and guidance, and, more generally, of information in all matters pertaining to tuberculosis as an infective disease. The wide scope and the utility of the institution showed themselves quickly. Within three years of its establishment it was possible, from an analysis of the first 1,000 cases, to deduce many interesting conclusions, and by means of a spot

* Allude to the Tuberculosis Society of Scotland on the occasion of assuming the honorary presidency of the society.

map to illustrate the widespread distribution of the disease in the community. This enforced the desirability of the notification of tuberculosis.

It took long, however, to have the value of the central institution recognized and the pattern adopted. In a discussion at the British Medical Association at Carlisle in 1896 on "Tuberculosis: Its Prevention and Cure," the new procedure was developed by me at some length, but the objective of such purposive effort towards the prevention of tuberculosis seemed to be regarded as of little significance, and no allusion was made to it in the printed report of the meeting. It is pleasant to recall that at the meeting I met Calmette for the first time; he had come to speak on the subject of antivenene. Our meeting had interest in the light of subsequent events.

Gradually the conception of the tuberculosis dispensary as the centre of activities caught on, and dispensaries, of varying quality, were established in several countries from 1901 onwards: in France under the influence of Calmette, Richet, and others, in Belgium (Malvoz), and presently in London, where the first tuberculosis dispensary in that city was established at Paddington in 1909. Thereafter, through the activity of the Central Fund for the Establishment of Tuberculosis Dispensaries in London, eleven dispensaries were erected in metropolitan boroughs.

All the time the field of operations of the tuberculosis dispensary was becoming wider, and its significance more apparent as the nodal point in any system for the treatment and prevention of tuberculosis as a communal disease. And so, gradually, there was developed what has come to be known as the Edinburgh scheme—tuberculosis dispensary, sanatorium, hospital for advanced cases, colony, etc.

From 1930 onwards I was fortunate in having opportunities to press the subject in a large number of cities at home, on the Continent, and in Canada and the United States. Then followed the work of the Departmental Committee on Tuberculosis under the chairmanship of Lord Astor, and ultimately the adoption of the uniform tuberculosis scheme throughout Great Britain.

Early Inquiries

In spite of the prevailing view, already referred to, that phthisis was worn threadbare, many clinical and bacteriological questions presented themselves in the early days. The laboratory was at first a very simple affair, adequate for the demands then made on it, including the development of methods of staining, enrichment methods for more easy detection of the bacillus, and various procedures for the rearing of cultures from discharges. Those questions included, more particularly, an inquiry into the actual cause of death in tuberculosis

—the subject of my M.D. thesis in 1887—which led to the conclusion, on experimental grounds, that death from tuberculosis is essentially referable to intoxication, which affects the circulation by way of the neuro-muscular system.

And here let me say that the existence of a well-equipped laboratory in close relation with tuberculosis clinical material is a primary need if valuable opportunities for the advance of knowledge are not to be lost. Further, there is much to be said for the establishment—at least in relation to every teaching centre—of an institution on the lines of Southfield, Edinburgh—that is a sanatorium-colony, where cases of tuberculosis at all stages and at all ages, from infancy to advanced life, can be under observation side by side. Only thus can the natural history of the infection be thoroughly appreciated.

As a learned physician and biologist of the first century A.D., Dioscorides, has said: "Any one who wishes to be a skilful herbalist must observe each plant at every stage of its growth and in various localities."

Notification

The facts obtained within three years concerning the distribution of tuberculosis in the city and the study of environmental conditions impelled me in an address in 1890 to press strongly for the compulsory notification of pulmonary tuberculosis:

"Were it adopted we should soon have most valuable confirmation—or let us suppose the opposite, although I do not think this latter likely—of the statements which have been made regarding the communicability of consumption and the tendency to its occurrence in certain houses and districts. Edinburgh will make a big move, and a move, I make bold to say, which will be speedily followed by many, if her medical officer of health will stimulate the authorities to this further development."

The immediate result was curious. Meeting the medical officer of health coming down the Mound two days afterwards, he remarked: "Don't throw yourself against a stone wall." And eighteen years later, the Chief Medical Officer of the Local Government Board of England, in his volume on *The Prevention of Tuberculosis* (1908), concluded that "it would be inexpedient, unwise, and of relatively little use to advise the general adoption of compulsory notification of phthisis. Public opinion is not ripe for this step, and such notification would remain to a large extent a dead letter." The "inexpedient, unwise, and relatively useless" procedure became the law of the land in 1912. Notification has developed without serious hitch, and, notwithstanding imperfections of personnel and machinery, has played an important part in the control and eradication of tuberculosis.

Tuberculin

It was during the meeting of the International Congress of Medicine in Berlin, in the summer of 1890, that I first heard whispers that Robert Koch was about to add to his earlier laurels by the discovery of a cure for tuberculosis. The actual announcement of tuberculin followed in December of that year. I recall, vividly, the hurried race from Edinburgh to Berlin during the winter session, and the warmth of excitement which contrasted amazingly with the icy coldness of Berlin at that season. Tuberculous patients—mostly in advanced stages—and doctors alike, who had flocked to the capital, were elated with high hopes. The medical world of Berlin itself was ranged in two camps, that of Koch with flying banners, and the other, conservative, swayed by attachment to the older conception of the disease. Yet, curiously enough, it was Professor Virchow himself—great protagonist of the older group—who generously introduced me to Professor Koch,

who in turn gave me a small flask of tuberculin for use "primarily in the interest of the Victoria Consumption Dispensary."

You are all more or less familiar with the "ups and downs" of the controversy which raged for long regarding tuberculin in the realm of therapeutics. As one who, ever since the announcement in 1890, has retained unfaltering belief in the greatness of the discovery—second only to that of the tubercle bacillus itself—I crave you will bear with me when I emphasize, in a few words, its far-reaching significance in relation to our knowledge of tuberculosis. I shall confine myself to two broad considerations.

Tuberculin and the Epidemiological Conception of Tuberculosis

From the epidemiological side the knowledge obtained by means of tuberculin has revolutionized our entire outlook on tuberculosis. That seems a strong statement. If it not a whit too strong. The application of tuberculin throughout the countries of the world has burst the conception of tuberculosis as a disease—admittedly infective—occurring in certain individuals, especially at certain age periods, and more prevalent in certain climates.

It has demonstrated the universality of infection, sooner or later, under ordinary conditions, in civilized lands. It has demonstrated that, for the most part, the infection is contracted early in life, and it has shown that the influence of that infection—for better or for worse—is maintained throughout the life of the individual. It has convincingly proved that neither latitude nor climatic conditions, as such, seriously alter liability to infection and the consequences of infection. It has shown us that these are dependent, on the one hand, on the presence of infected persons or cattle in the community, and, on the other, on environmental conditions of varying kinds, which may favour or antagonize the effect of infection in the given individual.

Tuberculin and Diagnosis

The diagnosis of the disease in the individual has, through tuberculin, been placed on an entirely different plane from that previously possible. Observations in the experimental animal and in cattle, as in the human subject, have shown that the fact of infection may be determined within a very short period of the date of infection. The value of this in relation to experimental work is of first-class importance. For the farmer the tuberculin reaction is the basal fact on which rests the possibility of establishing a tubercle-free herd. It is indeed fundamental to the eradication of tuberculosis from the bovine population, an attainment pre-eminently desirable from the agricultural, not less than from the medical, point of view.

With these facts in mind it seems extraordinary that, in spite of strong and repeated advocacy of the application of tuberculin to the human subject, the efficacy of the proposal has been so little appreciated. We know that tuberculosis is likely to occur sooner or later in all family groups. We have in our hands a means of determining exactly—that is, within a few weeks—the date when infection is contracted. This knowledge is pregnant with meaning for the future of each individual; it makes possible the interpretation of events, the significance of which would otherwise be missed. The means by which the information is obtained is simple, free from pain, and free from risk of any kind.

My plea has long been that this test—confirmatory or otherwise of an event of such importance—should be carried out in routine fashion by every family practitioner at successive intervals from the period of infancy onwards. The chief value of the test lies in the determination of the approximate moment of infection. To wait

for the application of the test until some doubtful issue presents itself, or until school age, is to wait too long and to lose most of the advantage. From the moment that a positive reaction has first been given both doctor and parent are placed in possession of an invaluable key to the meaning of further events in the child's life. From countless observations I am convinced that, if the key be understood and applied properly, it is possible thereby to anticipate and exclude the graver consequences of the initial infection. I confidently look forward to the time when such procedure will form part of the ordinary preventive practice of the family practitioner. Recognition of the possible effects of tubercularization, and the timely adoption of methods of *detubercularization*, would mean the gradual disappearance of the grosser forms of tuberculous disease—both skeletal and visceral.

Turn again, for a moment, to the immediately therapeutic side. This was the central point round which the more material expectations revolved when tuberculin was first announced. In 1890 clinicians and pathologists were chiefly concerned with pronounced changes in tissue and function. The debacle which followed was chiefly due to exaggerated hopes. It seems almost incredible to recall the aspect of patients who, in late stages of disease, flocked to the tuberculin flask as to a sacred pool of healing. The diseased lung, frequently disorganized beyond recall, was to be reintegrated as by magic and the flickering life of the intoxicated body refreshed and stabilized at command. The unscientific attitude met its nemesis in the post-mortem room. Professor Virchow said to me he had never seen such grossly congested organs in all his pathological experience.

The effective value of tuberculin had not yet emerged—although in justice to Koch it should be recalled that, from the first, he spoke of its application to early cases. Time was required for the realization that the value of tuberculin lies essentially in its power of early detection, and that its properties are exercised especially in the way of limitation and prevention of spread.

Looking through the records of the continuous use of tuberculin during more than forty years, in hospital and private practice, I remain deeply impressed by the mass of evidence pointing to its therapeutic efficacy. It will suffice to recall that I have seen tuberculous disease in almost every part of the body yield remarkably during the continued use of tuberculin. By way of examples may be cited tuberculous ulceration of the epiglottis (on account of which tracheotomy had been performed); tuberculous infiltration of the ventricular band, obstructing respiration to such an extent that thyroidectomy had been recommended; renal tuberculosis with involvement of ureter and bladder; large tuberculous masses in the abdomen; and glandular tuberculosis (in some cases with alarming pressure symptoms), for which extensive operation had been repeatedly undertaken. Many such cases have reported themselves from time to time without any sign of retrogression.

Examination of Contacts

One of the earliest developments in connexion with the tuberculosis dispensary was the systematic examination of family groups, or, as it was called in early days, the "march past" of the contacts. The "march past," as we baptised it for rhetorical purposes, was anything but a formal affair. It took time and involved careful discrimination on physical evidence—all this before the introduction of tuberculin tests. It was the careful systematic examination of these family groups which led me to lay especial stress on thorough examination of the lymphatic system at every available point, and enforced the significance of minor degrees of glandular enlargement.

It was especially interesting to observe the support obtained by the tuberculin test for views regarding the wide dissemination of tubercle among children which had been formed by me in pre-tuberculin days by application of the older physical methods. Resting on earlier methods one had made the statement (vide *The Anti-Tuberculosis Programme: Co-ordination of Preventive Measures*, Washington, 1908) that 30 per cent. of school children (unselected) presented stigmata of tuberculosis. These figures, when reported, were made light of by some authorities. When tuberculin came along, its application in routine fashion among children went to show that the percentage reported as tuberculous on the older line of evidence was much within the mark. The systematic examination of contacts with the aid of tuberculin is one of the most vital parts of the work of the tuberculosis dispensary, and will continue to be so until such time as it becomes the duty of the family doctor to make the routine tuberculin tests at the successive intervals of which I have just spoken.

Mode of Entrance: Misleading Conceptions

The extended observations it has been possible to make during so many years—clinical, pathological, and experimental—have growingly ripened my belief that the view usually held regarding the contraction of tuberculosis by the entrance of bacilli through the respiratory tract, with resulting primary focus in the lung, is narrow and misleading. Repeated experimental observations have convinced me that tubercle bacilli can pass into the body by a variety of channels, and that, while the passage of tubercle bacilli through the skin is commonly associated with induration at the point of inoculation, the passage of bacilli may occur through mucous membrane at almost any point, leaving little register of disturbance at the point of entrance.

All these observations go to emphasize the views I have taught for many years, and which I developed in the introductory address given to this society at its first meeting in November, 1921. In that address I summarized the conclusions previously formed by me as to the stages of infection in tuberculosis, and to these I adhere to-day:

"While, if entrance occurs through the skin, the event is commonly registered by a definite sore, an obvious lesion is seldom traceable when inoculation has been effected by way of the mucous membrane, as may be the case at any point in the alimentary tract from the lips to the anal orifice, or in the respiratory tract from the nostril to the ultimate alveolus.

"The absence of local lesion is likely when infection occurs, as it oftener does, during the tender period of developing childhood. At that date the mucous surfaces are rapidly absorbent and succulent, and the entrance of the tubercle bacilli may leave little, if any, trace. Theoretically, especially at that age, the possibility of entrance at any point of the mucous surface must be admitted, but the greater vulnerability of certain points, notably the tonsillar region, including the posterior nares and fauces, will be kept in view."

Since the date of the first meeting of the society I have repeated a number of observations on slightly varied lines. They all lead to the same conclusion, that, by whatever channel the tubercle bacillus obtains access to the body, whether through the skin or mucous membrane, its further passage throughout the system is effected for the most part by lymphatic spread. This is the case in the infant and young child, as it is the case in the calf and other animals. In both instances I am satisfied that the tubercle bacilli are not, for the most part, swallowed or inhaled (as is usually believed), but are introduced by more immediate passage through the buccal or nasopharyngeal mucous membrane from the contents

of these cavities, to which bacilli have obtained entrance in the course of fondling, feeding, etc. The commonly accepted division of the channels of infection into respiratory and alimentary is, in my judgement, arbitrary, and untenable in view of the facts. That infection can be effected in the experimental animal by either route there is no manner of doubt. It must be kept in mind, however, that the conditions under which spontaneous infection is effected differ widely from the methods of the experimental laboratory.

Undue Dominance of the Lung in the Problem of Tuberculosis

Paradoxical as it may seem, the tuberculous lung has been a chief obstacle to the development of a scientific conception of the natural history of tuberculosis. From earliest times the attention of the physician—as also of the man in the street—was directed towards the classic picture of the consumptive patient gravely ill or dying from disease which was apparently centred in the lung. "Phthisis" was regarded as essentially a disease of the lung.

In the circumstances it was most natural for the pathologist, like the clinician, to direct his attention to the lung as the chief subject of investigation. Generation after generation has approached research from the same angle. Observers have differed only at successive periods in their interpretation of the morbid appearances. The dominating position accorded to the lung has obscured the truth. The clinician has seldom got away from the lung as the central feature for study and care. Tuberculous manifestations elsewhere have been regarded as complications, of what was conceived to be the primary or essential lesion. Face to face with appearances which implied, or might imply, tuberculosis in other parts of the body, he has continued to turn to the lung for corroboration or otherwise of the diagnosis. And at the post-mortem table there has been much the same outlook.

This faulty attitude has been strongly impressed on me as a physician by the frequently recurring reference from colleagues in special departments regarding obscure conditions of ill-health, or less common appearances in particular organs, as to whether the lungs showed evidence of primary disease. This outlook has continued throughout successive decades in my experience, and is still largely prevalent. It is a grave misconception of the order of events.

The misconception has not only coloured observations at the bedside and in the post-mortem room: even the experimental pathologist has been influenced unduly by the older line of thought. It was assumed that the diseased lung became infected by the direct entrance of the bacilli through the respiratory passages. Attempts to reproduce the disease were arranged on these lines; I did a good deal of that sort of thing in the early days. With the quantities of bacilli used for experiment it was speedily found, as might have been expected, that pulmonary tuberculosis could be produced in this fashion. On the other hand, it was speedily shown that when tubercle bacilli were introduced in quantity into the gastro-intestinal tract, tuberculous infection was likewise readily induced—some observers regarding it as the readier avenue. Thus arose the opposing doctrine of respiration *versus* ingestion. Nor has the difference between the two schools been adjusted.

Again, the assumption that infection is effected for the most part by way of the respiratory passages led to the vexed question of "dust" *versus* "droplets." Here, too, confusion of issues occurred, and the very natural conclusion resulted that either means was possible, provided that the dust or droplet contained the essential tubercle bacillus.

Lessons of Comparative Pathology

The sequence of events in the human subject is not dissimilar to that in cattle. Involvement of the lung is, for the most part, a late visceral manifestation of an infection contracted very simply at a much earlier date. The prevailing habit of separating between pulmonary tuberculosis and non-pulmonary, which at one time may have served some purpose, is unscientific and misleading. No less so is the curious habit adopted by many of speaking of "surgical" tuberculosis as opposed to "medical."

Similarly fallacious is the attempt to associate certain manifestations of tuberculosis too precisely with one or other type of bacillus. Twenty-five years ago, the last time I met Robert Koch, he denied most stoutly, and with not a little heat, that bovine infection of the human subject could result in pulmonary tuberculosis. Involvement of the lungs, he maintained, was always referable to infection by the human type. He regarded the two or three isolated statements made up to that date that bovine organisms had been recovered from pulmonary tuberculosis in man, as due to inaccurate observation. To-day, thanks especially to the insistent labours of Drs. Stanley Griffith and Munro, we have abundant proof that Koch's dictum was wrong.

In this connexion the post-mortem appearances in cattle at various ages are of particular interest, as is likewise the sequence of events in the inoculated animal. I have seen a congenitally affected calf, born of a mother whose uterus was literally studded with tubercle, presenting on the fifth day after birth, as the sole evidence of disease, a tuberculous gland at the hilum of the liver and another in similar relation to the spleen. We have fed a calf, born in a tubercle-free herd, and ascertained by tuberculin test at the date of experiment to be non-tuberculous, with milk to which an emulsion of tubercle bacillus (human) had been added, and in due course the tuberculin reaction became positive, and post-mortem examination revealed tuberculosis limited to the retropharyngeal gland.

Frequently at the slaughterhouse calves of 2 to 3 months old are to be seen with the lymphatic system literally packed with tubercle, and yet not a trace of involvement of lungs or pleura which, in the adult cow, constitutes ultimately the characteristic lesion. (For abundant opportunities for observation in this sphere I have been much indebted to the kindness of Mr. Arthur Gofton, F.R.C.V.S., chief veterinary inspector at Edinburgh.) The lessons of the slaughterhouse are most convincing—namely, that, apart from congenital disease, which is relatively uncommon, infection in the bovine species and in pigs commences in the glands related to the buccal cavity and the pharyngeal region, and this is followed by gradual extension throughout the lymphatic system. The mediastinal glands of the young bovine, which by reason of their size are much more easily studied than those in the human subject, may frequently be found grossly involved by tubercle, while hardly a trace is to be found in the lung.

The sequence of events in bovine tuberculosis is of particular interest. Prior to the recognition that tuberculosis in cattle was due to Koch's bacillus, emphasis was chiefly laid, and, indeed, is still laid by clinical veterinary officers, on the characteristic involvement of lungs and plenra. Yet the collective facts of that jealously guarded post-mortem theatre, the slaughterhouse, afford convincing evidence that involvement of the lung and pleura is actually one of the later results of tuberculous infection. Pulmonary tuberculosis is to be expected in the tuberculous cow, but it is relatively uncommon in the young calf.

I have no wish to press the facts of comparative pathology beyond the legitimate limit. They should not, however, be lightly discounted. They should be kept well in view in interpreting the facts of human pathology.

Better Perspective

I am, of course, well aware that the majority of opinion, pathological and clinical, favours—almost takes for granted—the view that human infection occurs generally by way of the respiratory passages, and that the primary focus of disease is to be expected, and is generally to be found, within the lung. I have followed with close interest the observations of distinguished workers in this part of the field, among whom members of this society hold an honoured place.

None the less, in this moment of recollection and survey, it seems right to make it clear that, starting both on the clinical and on the pathological side with the belief that in the great majority of cases the lung was the seat of primary infection, I have been constrained by an overpowering weight of evidence in my own experience—clinical, pathological, and experimental—to relegate the lung, from this point of view, to a secondary place. From what I have said regarding the undue dominance of the lung in current thought regarding tuberculosis it must not be supposed that I make light of the preponderating place properly accorded to pulmonary tuberculosis in the sphere of practical medicine. It is all the other way. As things now stand, pulmonary tuberculosis, which commonly occupies the final act in the tragedy begun by the silent entrance of the bacillus into the human body, demands still the utmost attention. So long as the entrance of the bacillus remains unwatched and unnoticed, and its progress remains unchecked, so long will the story of disaster tend to develop and pulmonary disease continue to be frequent.

The resources of medicine have, however, shown that the invading organism may be checkmated at many points before the last act is reached; and to effect this is the chief aim of the preventive measures which are embodied in the tuberculosis scheme of this country. And happily, even when the curtain seems raised for the last act, many variations have now been introduced into the old-world story. Pulmonary tuberculosis has been largely robbed of its more ominous features by early diagnosis, by the adoption of the physiological measures of the sanatorium, and by methods of frontal attack which are now possible by the combination of surgery with medicine. Thanks to modern technique, "defeatism" has disappeared and disaster is daily averted.

It is long since I satisfied myself, from innumerable observations, that infection in the child is effected, for the most part, neither by respiration nor by ingestion, as generally understood, but by more immediate recurring contact between the child and the infected individual, as in fondling, kissing, feeding, etc., and, likewise, of course—as most convincingly demonstrated by John Fraser, Mitchell, and others—through less direct contact with the cow by means of infected milk. Introduced from whichever source, the bacilli entering the mouth or nose tend to linger about the gums (teeth), and especially about the faucal and nasopharyngeal regions, from which they may pass through the mucous membrane without very obvious disturbance, and thence reach the lymphatic circulation; while in other cases the bacilli may pass lower down in the gastro-intestinal tract in swallowing tubercle-containing milk. Sometimes, doubtless, entrance may occur through the respiratory passages, but, on many grounds, I believe the latter to be relatively infrequent.

The first evidence that infection has been contracted may be found most frequently in enlargement of one or more, often several, glands in the neighbourhood of the

point of entrance, especially cervical glands. The enlargement is, as a rule, slight, and discoverable only by careful palpation along the likely lymphatic lines (not usually the obvious swelling, discovered by the observant mother, or the gross disturbance which commonly leads to a visit to the surgeon). The lymphatic involvement I have in view is of finer character, progressing insidiously from point to point. The search for this forms the first line of investigation in the case of a young child. By the time this glandular involvement is determinable the tuberculin reaction will generally be found positive, and the fact established that the child has been "tuberculized."

I might cite endless examples from children in illustration of these significant points. Let me recall to you a remarkable illustration from comparative pathology which carries the evidence further than is commonly possible in the child. The case, that of a cow, was recorded some years ago to the society by Dr. Simpson and myself (*Transactions*, 1924-5). The animal, one of our tubercle-free herd, which had always passed the tuberculin test, was grazing one day in a certain field into which, through carelessness on the part of a neighbouring dairy-keeper, a sick cow, recently under treatment for "pneumonia," was allowed to enter. "The dairy-keeper's cow was discovered there in a dying condition the following morning and, immediately after removal, died from generalized tuberculosis. These two cows, after the invariable manner of their kind, were seen to have licked each other by way of greeting. They were in contact in the field together nine hours." Our own cow, which on April 24th and on all previous occasions had passed a double tuberculin test, was tested some months after the incident referred to, on October 24th, and gave a very positive reaction. It was slaughtered immediately thereafter, and the necropsy showed definite tuberculous involvement limited to the retropharyngeal glands.

Let me resume briefly as follows. Tuberculosis, like other infective processes, is of simple origin. There is a moment in time when the tubercle bacillus passes the protecting barrier—the mucous membrane most commonly. This is followed by a latent period (primary incubation) while the bacillus is establishing itself within the lymphatic circulation. After an interval, not very certainly defined (perhaps three or four weeks) objective evidence may be found (clinical or post-mortem) in glandular enlargement, isolated or spreading. At this stage the process may be, or at least may appear to be, arrested.

Later, with wider extension throughout the lymphatic system, all kinds of incidents may occur—for example, extension of infection through propinquity, rupture into some passage, sac, or viscus (or there may be local exudation), any of these giving rise to obvious clinical effects. Finally, with the passage of bacilli into the blood stream, whether by the natural channel or more abruptly, as by entrance from a caseating focus or in the course of surgical operation, the final catastrophe of miliary spread is made possible.

The points in time at which such incidents occur, or reactivation of an existing focus takes place, vary endlessly, according to the resistance offered by the infected individual. This in turn is largely governed by environmental conditions (using that term in a wide sense), at successive age periods, or through accidental circumstances such as the advent of other infections—for example, measles, whooping-cough, and, it may be, through injuries. The occurrence irregularly of reactivation or extensions is usually registrable by clinical signs and symptoms. On the vexed question of the part played by the fresh entry of tubercle bacilli from without, time will not allow me to enter. In no subject in medicine

is it more desirable to maintain the biological outlook. We must think in terms of decades and generations. Once the tubercle bacillus has obtained a foothold whether, as rarely, during intrauterine life or at some subsequent date from infancy onwards, the possibilities resulting from bacillary implantation are manifold, and should be kept in view by the thoughtful physician without fuss or exaggeration.

If the influence of the harboured bacillus be frequently beneficial for immunity against further attack from outside, it is to be borne in mind that the bacillus is highly resistant, and may remain dormant for many a day, encapsuled perhaps in some out-of-the-way corner, still capable of reactivity and reproduction, and, given favouring conditions, of spread in all sorts of directions. No need for me in a company like the present to dilate on those favouring conditions which occur in numerous ways and at numerous stages in conventional human life. These occurrences explain much that were otherwise hard to interpret in the life-history of the tuberculous individual

and in mortality tables. It is when you have watched in countless cases the "ups and downs" in the persistent struggle between the invading bacillus and the resisting forces of the host—strong or weak as these may be from time to time—that you begin to understand the mystery of the drama of tuberculous infection, action and reaction, and the interlocking of successive events.

These are a few of the reminiscences and musings which remain with me from fifty years' wandering up and down in the wonderful garden. These rambles have occupied a large part of my life and have brought both pleasure and solace. You have given me the privilege of recalling these happy times aloud. Your kindness in inviting me and in listening has enhanced the pleasure of recollection. I hope that I have not wearied you or unwittingly trodden on anyone's toes, or seemed to make light of the labours of others in the garden. Their friendliness and good will have made me happy, and my admiration of their successful efforts has been unbounded.

PARASITIC DISEASES COMMON TO MAN AND ANIMALS*

BY

THOMAS W. M. CAMERON, M.A., D.Sc., Ph.D.Ed.
RESEARCH PROFESSOR OF PARASITOLOGY, AND DIRECTOR, INSTITUTE
OF PARASITOLOGY, MCGILL UNIVERSITY, MONTREAL

Human beings have acquired their parasites from two main sources: from their own simian ancestors and from environmental circumstances, the most important of which is association with animals. It is not always possible to place any given parasite immediately in its own special category—inquiries into the distant origin of animals and plants must always contain an element of speculation—but most of them can be catalogued with some degree of accuracy. To the first category belong such parasites as malaria, filaria, and pinworms, while to a borderline group between it and the second category belong the hookworms and similar forms, which have very close relations in domesticated animals, but which, acquired in very early days, have now become exclusively human. It is interesting to observe that the human *Ascaris* and *Necator* are probably undergoing a reverse process of evolution, and are becoming parasites of pigs as well as of man.

The purpose of this paper is to discuss parasites which even now are being carried to man from animals, especially animals to be found in Canada. In parenthesis it may be mentioned that all such forms as occur in animals in Britain also occur in Canada. Like the white man in North America, they also were immigrants. However, this continent provided its own quota, and the forms discussed here include a few which are not found in the United Kingdom.

For purposes of convenience we may consider these parasites in the following groups: (I) those which live as adults both in man and in animals; (II) those which live as adults in man and as larvae in animals; and (III) parasites which live as larvae in man and as adults in animals.

GROUP I

The group of parasites living as adults in man and in animals can be subdivided into two, the first division including forms which are sufficiently frequent in human

beings to be considered as "normal," and the second including forms only rarely found in man, which are obviously "accidental" parasites.

"Normal" Parasites

The broad tapeworm (*Diphyllobothrium latum*) of man and carnivores has been known for a long time in Europe, where its modern endemic focus is in the Baltic area; it also occurs, however, in Switzerland and Ireland. It was introduced to the North American continent many years ago, and is now located mainly around the Great Lakes and other lakes from Ontario to Alberta. A number of cases of infection with this parasite have been recorded from New York; but the source appears to be pike from the Great Lakes. The incidence of the tapeworm in Canada is rapidly increasing, and the fact that it infects a variety of wild mammals, such as bear and mink, as well as domesticated ones makes control much more difficult.

The eggs of the tapeworm are passed in the faeces into water, where in due course they hatch. The larvae are swallowed by minute water fleas (*Diaptomus orregonensis*), in which they undergo a certain amount of development: this is completed when the first host is swallowed by a fish. Quite a number of fresh-water fish can serve in this way, but the most important is the pike (*Esox lucius*). The infective stage is reached in the fish, especially in summer, and particularly in medium-sized or smaller specimens. Infection results, of course, from eating raw or improperly cooked fish. This worm is generally associated with a form of anaemia, but the latter is certainly not present in all cases, although there is evidence that the worm does cause a small increase in size of the red cells. There is a distinct eosinophilia in the early stages of the infection; this reaches its maximum about the time of maturation of the worm, after which it rapidly diminishes almost to normal.

The presence of the parasite in Canadian fish is of some importance, and every effort should be made at control: (1) by keeping summer-caught pike off the market; (2) by cooking or freezing fish for consumption by both man and animals; (3) by discouraging the feeding of raw fish to dogs; and (4) by periodically dosing the latter for tapeworms. In the presence of wild reservoir hosts absolute control is difficult, but any steps to prevent the pollution of lake water with infected faeces should be of assistance in reducing the incidence.

The human whipworm, *Trichocephalus trichiuris*, which is quite cosmopolitan, but nowhere very common or serious, also occurs in pigs, while the dwarf tapeworm, *Hymenolepis nana*, which is fairly common in the Southern States, is probably identical with the form found in rats and mice in Canada. The dog flea occurs

* An address delivered before a joint meeting of the Central Canada Veterinary Association and the Ottawa Medico-Chirurgical Society, at Ottawa, April, 1934.

frequently on man, and the human flea on the dog, so that both of these parasites may also be included in this section. The human lice, on the other hand, are peculiar to man, and none of the animal forms can find more than a very temporary lodging on him.

Abnormal Parasites

A very large number of parasites of animals have at one time or another been recorded in man. Many of these are of purely academic interest, but a few occur with sufficient frequency to enable us to regard the animals as "reservoir hosts" for these parasites.

The number of species of *Paragonimus* is still far from being settled, although the consensus of opinion is that probably all are variants of a single form. However, it seems advisable to retain the name *P. kellicotti* for the species of lung-fluke which occurs in North America. Here the normal host is the mink, but it is also common in the musk-rat, and it has been recorded from pig, dog, cat, wild cat, goat, and man. Its distribution in Canada is still very incompletely known, but it seems to be fairly widespread, especially in the east.

The eggs, coughed up, are swallowed and passed to the exterior in the faeces. In about three weeks they hatch, and the larva gains admittance to the operculate snail *Pomatopsis lapidaria*. This snail is amphibious, so that the eggs on damp ground, as well as in water, have an opportunity of continuing their life-cycle. From three to four thousand cercariae emerge from the snail in about three months after infection, but they develop further only if they are able to penetrate into the thin chitin between the segments of crayfish (*Cambarus spp.*). In the second intermediate host they proceed to the heart region, where they become encysted. (In the Asiatic species they are often found in the musculature.) These continue to develop after encystment, and several weeks may elapse before they become infective.

Infection is by eating the crayfish in an uncooked condition, when the young flukes penetrate the intestinal wall and migrate directly to the lungs. Needless to say, many worms never reach their final habitat, and they are occasionally found alive in various other parts of the body.

Human beings may act as accidental hosts for the liver-flukes of sheep, but this is very rare, and there is reason to believe that many of the recorded cases, which were diagnosed from the presence of eggs in the droppings, were not really infected. The eggs are merely contaminations of liver eaten as food, and are in course of leaving the body. The liver-flukes usually found in man and carnivorous animals belong mostly to the family Opisthorchidae, and while the only genus commonly seen in human beings is *Opisthorchis* (including *Clonorchis*) there is every reason to believe that, given the opportunity, any one of the members of this family could attack human beings. All appear to be fish-carried, and in certain parts of the Far East and in Northern Asia and Northern Europe, where conditions are quite analogous to Northern Canada, human infections are very common. The two genera so far found in North America are *Opisthorchis* and *Parametorchis*; there is increasing evidence that the latter is of considerable importance to dogs in the North. A heavy infection causes progressive weakness, emaciation, and anaemia, and its significance in an animal which provides the sole method of transportation for many months of the year can well be understood.

The members of this family, in addition to the usual snail intermediary which all flukes require, have a second intermediate host in fish. The cercariae which escape from the snail encyst on scales or in the flesh of various species of fish, and the definitive host is infected by eating this. The available evidence suggests that any fish-eating animal may be infected. Man owes his freedom, as a rule, to cooking, as heat quickly destroys the cysts. For this reason fluke is not common in human beings here, but it must be admitted that very little search has yet been made for it. Accordingly, the parasites must be considered as of potential human, as well as actual veterinary, importance.

Dipylidium caninum is an exceedingly prevalent parasite in dogs and cats, which also occurs in children: in fact,

it is probably the commonest human tapeworm seen in Great Britain. The intermediate stage is found in fleas and dog lice, and these are occasionally swallowed by children. It is not a very dangerous parasite, but its presence in children indicates that, hygienically, all is not as it should be. Children also become infected with several species of ascarid worms found in dogs and cats. Here, of course, infection is produced by swallowing the embryonated egg, and implies opportunities for faecal contamination of food or utensils.

The genus *Trichostrongylus* includes a number of very small parasites related to the hookworms living in the alimentary tract from the stomach to the caecum. They have a wide geographical range and live in a great variety of mammals. Their main hosts are domestic ruminants and, possibly, horses, but there are a number of records from man; probably these could be greatly increased if examinations were made more frequently. The life-cycle is somewhat similar to that of the hookworm, except that infection is mainly by ingestion. The eggs resemble those of the hookworms, but can be fairly easily distinguished. It is doubtful if these parasites do much harm to human beings.

Man is sometimes infected with mange mites from the lower animals (particularly *Sarcoptes*), chiefly from horses, cows, and dogs. All the species in this genus are similar morphologically, but strains appear to have evolved for each species of host, and so human infections are generally very amenable to treatment with sulphur dressings. The human strain is much more resistant to treatment, however.

GROUP II

Of the parasites living as adults in man and as larvae in animals *Taenia solium* and *Taenia saginata* are both exclusively human parasites in their adult state. The larva of the former, however, is found in pigs (*Cysticercus cellulosae*), whereas that of the latter occurs in cattle (*Cysticercus bovis*). Their distribution, therefore, corresponds with the distribution of these two animals, but their frequency depends on whether or not meat products are habitually eaten uncooked or only slightly cooked. *Taenia solium* is, accordingly, commoner in Germanic and similar communities, whereas *Taenia saginata* is more often seen than *Taenia solium* in Anglo-Saxon peoples. Both occur in Canada, although their distribution is somewhat erratic. Osler found *Taenia solium* in Montreal, and there are recent records of its local frequency in the Slav communities in the west. It is, of course, a rare parasite in Great Britain and elsewhere among people of British extraction—reports to the contrary notwithstanding—because of their habit of overcooking pork. *Taenia saginata* is found in Great Britain, and, although we have little information of its exact distribution in Canada, it also is most frequent in the west; however, it is quite generally distributed elsewhere, although never very common, as in Britain. *Taenia solium* is quite a dangerous human parasite, as its larval stage can develop in man as well as in pigs; it does not always choose the musculature, but is found subcutaneously or in the central nervous system. Quite a number of cases of lunacy are attributable to it. There is no such danger with *Taenia saginata*.

The Trichina Worm

The most important of the parasites which produce trichinosis in man is the trichina worm, or *Trichinella spiralis*. The parasite itself was only recognized in 1828, when Peacock observed the larvae in London, but it was thirty years later before Zenker was able to show its connexion with the serious disease with which we now associate it; at one stage it caused more public apprehension in Germany than did cholera. For some ten years American pork was excluded from Germany on this account, and from this the present very efficient American system of meat inspection directly resulted.

Canadian as well as British meat inspection ignores the possibility of trichina infection of pork, and no attempt is made to search for it. However, in Europe, elaborate measures are taken and large staffs and special apparatus are employed for this purpose. The importance of trichina

infection depends entirely on the habits of the people. Where raw, undercooked, or smoked pork is customarily eaten it is a parasite to be feared, and it is in nations with such habits that we encounter it most commonly. Where, however, as in Anglo-Saxon countries, it is customary to overcook all pork and pork products, the dangers are negligible; this precaution is probably more effective than the most perfect system of meat inspection, which, after all, may merely lead to a sense of false security. In the United States, where a fair proportion of pigs are infected, there have been about 2,000 human cases reported since 1842, although the actual numbers infected but not diagnosed must be very much higher. Most cases are traceable to the consumption of raw sausage or ham, usually prepared at home or in small establishments. Where pork is prepared on a large scale the dilution of the worms is generally such as to make infection negligible and too small in amount to cause disease. Practically all these American cases were confined to people who had still retained their Central or South European habits, while those of British or French origin were not affected. Quite a number of cases have had their origin in the eating of bear flesh, and we have found the trichina worm in a variety of wild carnivores. It is, of course, essentially a parasite of flesh-eating mammals, and in certain parts of the United States it is fairly common in dogs and cats.

Generally, the disease is chronic in the pig; in fact, there may be no symptoms at all and the flesh is unchanged macroscopically. It is unnecessary here to discuss the course of the disease in man, but it may be of interest to draw attention to the frequent diagnosis of typhoid fever or "ptomaine" poisoning in the acute cases, and to "rheumatism" in the subacute later stages of trichinosis. Like most parasitic infections, in the earlier stages there is observed considerable eosinophilia, which, in this case, may reach as high a figure as 40 per cent. Sir William Osler was probably the first to draw attention to the great diagnostic value of this fact.

The distribution of the trichina worm in Canada is unknown, as it is in Great Britain. Human cases are occasionally recorded, but it must be remembered that symptoms are directly proportional to the numbers of parasites ingested. Cases with slight infection probably show no symptoms at all, are not likely to come to the attention of the physician, and still less likely to be diagnosed as trichinosis.

GROUP III

All the parasites living as larvae in man and as adults in animals are obviously "accidental" forms, although some are of very great importance, such as hydatid cyst, fluke larvae causing cercarial dermatitis, and hookworm and other larvae causing "creeping disease."

Hydatid Infections

Echinococcus granulosus as an adult lives in carnivorous animals, the dog being considered the commonest host, but wild Canidae are often infected and play no small part in its spread; cats are only infrequently infected. The intermediate hosts are legion; practically any mammal may harbour the hydatid cyst. Sheep are most often infected, but horses, pigs, and wild ruminants, such as the moose, are also important hosts. The disease is therefore essentially one of pastoral countries. There sheep constitute a large reservoir from which dogs are continually infected, and the opportunities for human infection are thus enormously increased. Although in human pathology hydatid is generally studied in the adult, it is in youth or even in infancy that the disease is usually contracted. Accordingly, in most cases, the cyst of the adult is one already old—a fact which explains the great proportion of abnormalities found in human hydatids.

It has been considered that drinking-water was the commonest source of infection, but *echinococcus* eggs, like most other helminth eggs, do not float in water in the state in which they are usually passed in the faeces. The drinking of surface water should not, therefore, cause infection. Contagion occurs most frequently through contact with dogs, especially by acquiring dried eggs on the

hands from a dog's coat contaminated with dried faeces. Faecal contamination of foodstuffs, particularly vegetables, is also probably a common source of infection.

Cercarial Dermatitis

The infective stages of a number of trematodes gain admission to the host by actually penetrating the skin. The most important of these are the blood-flukes or bilharzia worms. If they penetrate the skin of the correct host they continue to develop to maturity; if, however, they happen to have entered the skin of an unsuitable host, they die. Unfortunately, whether they are in the correct host or not, they cause a pronounced reaction at the site of entry, and the name "cercarial dermatitis" has been given to the resulting lesion.

There are no human flukes in north temperate climates which have such a mode of entry, but quite a number of wild birds and mammals are so affected. Their larval stages are common in many lakes, both in Canada and in the United States, and closely related forms occur in many parts of the British Isles and elsewhere. These minute cercariae have consequently become a considerable source of annoyance to bathers, and in some localities are so bad that fully half the people entering the water become affected. The condition starts with a prickly sensation a few minutes after exposure to infection, and urticarial blotches quickly develop round the site of entry. The itching may be intense, and papules or even pustules appear. In as little as four or five days the sores disappear with simple treatment, but in some cases they persist from four to seven weeks. The lesions vary to some extent with numbers, dirtiness of the water, and scratching, as well as individual susceptibility, but the history generally makes the origin of the disease obvious.

Analogous to cercarial dermatitis is the condition called "creeping eruption," in which a variety of parasites of lower animals penetrate the skin of man, and, finding the environment unsuitable, move about in or under the skin. Chief among these are immature hookworms of dogs and cats. While a number of these are present in northern latitudes, we have few records of the condition from there. It has been shown that relatively high temperatures, sufficient to cause visible perspiration, are favourable for the disease, and this may account for the fact that it is most frequently found in the south.

CONCLUSION

Of the parasites commonly found in man in north temperate climates only pinworms (possibly ascarids) and lice are exclusively human. Practically all the others are associated in some way or another with lower animals. The broad tapeworm carried by fish is also found in dogs, cats, and wild carnivores; the whipworm occurs in pigs; the two taenias and the trichina worm are conveyed to man by pork or beef; and hydatid cyst is the larval stage of a dog tapeworm. All of these, as well as cercarial dermatitis, are of considerable public health interest. Of potential importance in Canada are the lung-flukes and liver-flukes of carnivores, *Dipylidium* (the common urban tapeworm of dogs and cats), and the mange mites. It must be remembered, however, that modern parasitology is still a very young subject, and as it develops many more forms will probably have to be added to this list. Most of these parasitic diseases are easily preventable; in fact, the evolution of modern civilization and the activities of the sanitarian, the veterinarian, and the cook have already done much to reduce their incidence. Many, however, are still with us, and it is important to know not only where they occur but how frequently they occur, in order that adequate public health measures may be taken. Bacterial diseases are coming more and more under control, and the education of the public has done much to bring this about. Similar steps with regard to the animal parasites should have similar results, and there are signs that such steps would be not inopportune. These are particularly necessary in communities where habitations are widely scattered and sanitary services, so effective in our towns, are still in a rudimentary state.

AND

DAVID FYFE ANDERSON, M.B., M.C.O.G.

ASSISTANT TO THE REGIUS PROFESSOR OF MIDWIFERY, UNIVERSITY OF GLASGOW; ASSISTANT OBSTETRIC SURGEON, GLASGOW ROYAL MATERNITY AND WOMEN'S HOSPITAL

It is a common experience in medical practice that specific clinical rarities are seldom encountered singly. A striking illustration of this is furnished by the two cases to be described, which were admitted into our unit of the Glasgow Royal Maternity and Women's Hospital within a period of twenty-four hours. They proved to be examples of that rare variety of gestation designated "angular" pregnancy, which we are inclined to think has never received sufficient recognition as a definite clinical entity.

CASE I

A woman, aged 32, pregnant for the sixth time, was sent into hospital on November 12th, 1933, as a case of ectopic gestation. The fifth pregnancy, in 1929, had ended as an abortion at two months. In each of the first four deliveries, three of which were instrumental and the fourth spontaneous, the noteworthy feature was delay in the third stage. With each pregnancy there was complaint of increasing weakness. Menstrual periods had been irregular as regards both frequency and duration, but the patient was quite definite that the last occurred on July 23th. On the morning of admission there was a sudden gush of watery discharge (suggestive of rupture of the membranes), and acute pain developed in the right side of the abdomen. Pain thereafter was persistent; the patient felt cold and shivery, but she did not have any vaginal bleeding.

On admission she appeared to be extremely ill, being cold, pale, restless, and complaining of severe abdominal pain, mainly right-sided. There was no distension of the abdomen, but a rounded swelling, tender to touch, was present on the right side. The lower part of the abdomen was also tender, and marked Blumbergism was evident. No dullness was detected in the chest, but the respiratory murmur was harsh and accompanied by a few coarse rales. Bimanual examination showed that the cervix was closed, and that the size of the uterus corresponded to the stage of gravidity suggested by the period of amenorrhoea—namely, fifteen weeks; in addition, there appeared to be a cystic swelling to the right of the uterus.

A provisional diagnosis of ectopic pregnancy or ovarian cyst with torsion of the pedicle was made, and, in view of the evidences of peritoneal irritation, immediate laparotomy was performed under general anaesthesia. No blood or free fluid was found in the abdominal cavity. The ovaries were healthy, and the tubes, while somewhat congested, presented no abnormality. The intestines were normal and the appendix innocuous. Examination of the uterus, which contained no fibroids, showed marked elongation of the right cornu, and the diagnosis of angular pregnancy was established. The abdomen was closed.

The following day, November 13th, at 11 a.m., the patient had a rather prolonged rigor during which the temperature rose to 106°. The sputum, scanty and muco-purulent, was found to contain abundant pneumococci of Type IV. With the subsidence of the rigor, the temperature fell abruptly to normal and remained so. Incidentally, had serum been administered without typing the organism the satisfactory result would probably have been ascribed to that agent. Complete abortion occurred on November 14th at 2 a.m., after which the patient felt much better. Subsequent progress was uneventful, and she was dismissed well on December 2nd.

CASE II

A primigravida, aged 21, was admitted to hospital on November 13th, 1933, on account of violent, cramp-like pains in the lower abdomen, especially on the right side. The pregnancy had been uneventful until six days previously, when she had had her first experience of these violent pains. At that time her doctor had noticed that there was tenderness over the uterus, which extended to the right side. He had also noted the hardness of the uterus, and what appeared to be a purulent vaginal discharge, but there was no haemorrhage. With rest and thorough evacuation of the bowels the severe pain passed away, but the cramp-like ones persisted, culminating in the violent right-sided abdominal pain which necessitated removal to hospital. The patient mentioned that, from the onset of pregnancy, she had experienced pain radiating down the posterior aspect of the left thigh, but this did not incapacitate her in any way, and was probably unrelated to the obstetric condition.

She was afebrile on admission, but the pulse rate was increased. Inspection of the abdomen revealed a swelling lying obliquely towards the right side. Palpation confirmed this observation, and demonstrated the marked tenderness, especially over the upper pole, which occupied the right side of the abdomen below the umbilical level. On bimanual examination the elongated and tender right cornu of the uterus was made out, the patient was deemed to be about nineteen weeks pregnant, ectopic pregnancy and other abnormalities were definitely excluded, and angular pregnancy was diagnosed. Repeated examination of the urine for pus cells and organisms yielded negative results. The sedimentation rate of the erythrocytes was normal. Four days after admission the patient was seized with acute right-sided abdominal pain, which caused her to be doubled up. Temporary relief followed a large bowel movement, but the severity of the pain afterwards necessitated the administration of morphine.

The patient was allowed home on November 25th, and was kept under close supervision. Occasional bouts of right-sided abdominal pain occurred, but on the whole she remained fairly comfortable. The uterus continued to occupy its oblique position as the right-sided enlargement became progressively more marked. It was determined that, after the delivery of the child, the uterus should be manually explored in order to localize the placental site. On March 19th, 1934, she was readmitted on account of the recurrence of cramp-like abdominal pains; in addition, she complained of constant generalized pain in the abdomen and lumbar region. She was now thirty-five weeks pregnant; the uterus was lying obliquely, with the upper pole to the right, over which there was exquisite tenderness, and this part of the uterus was so tense as to suggest the presence of the foetal head.

On March 21st, at 7 a.m., the patient complained of severe abdominal pain, which increased in severity until at 10.30 a.m. she was in such agony that morphine had to be administered. The uterus at this time was uniformly tense and tender, but no contractions were observed. Definite labour pains began at 9 p.m. At 12.15 a.m. on March 22nd the cervix was found to be practically fully dilated, and the membranes were artificially ruptured. An hour later a male child, 17 inches long, and weighing 5 lb. 1 oz., was delivered with forceps. After extraction of the child, the uterus continued to lie markedly towards the right side. According to plan a hand was introduced into the uterus; the placenta was found to occupy the elongated right cornu, while the corresponding left cornu at a lower level was quite clear. Bystanders with a hand on the abdomen had no difficulty in appreciating the difference in level of the cornua, and the ease with which the observer's fingers could be felt in the left as contrasted with the right cornu was striking. The placenta measured 9 inches by 4½ inches, and had the shape of a large kidney; there was no evidence of retroplacental haematoma.

The progress of the patient was entirely satisfactory, and she was dismissed well on March 31st. Involution was progressive, but the marked elongation of the uterus to the right side, together with tenderness to the most gentle touch, remained noteworthy features for the first five days of the puerperium.

Remarks by Professor Munro Kerr

Many years ago I directed attention to the subject of angular pregnancy—namely, that particular variety of gestation in which the zygote becomes implanted in the angle or cornu of the uterus. The exact implantation site would appear to be either directly over the tubal opening, or, more probably, in the interstitial portion of the tube immediately external to that opening. The condition is quite distinct from the typical interstitial variety of ectopic pregnancy, for the ovum develops not in *substantia uteri* but towards the uterine cavity. The term "angular" has been employed by several writers in order to distinguish it from "interstitial" pregnancy on the one hand and "cornual" pregnancy on the other, as the latter term is often used to describe a pregnancy in a horn of a uterus bicornis.

In addition to the two cases described, I have seen four which were definitely proved examples of angular pregnancy, and a number not so typical but nevertheless suggestive of this specific abnormality. One of these four cases I described many years ago, but the story bears repetition, and is as follows:

I was asked by a medical friend to see his wife, as he feared she was threatened with an abortion. I had attended the lady at her two previous confinements—one seven and the other four years previously. When I visited her she gave me the history of a period missed. She also told me that ten days after the period was expected abdominal pain and haemorrhagic vaginal discharge appeared. The discharge was not great, but the pain was sometimes severe, and was more marked towards the left iliac fossa. Upon making a vaginal examination I discovered that the uterus was enlarged, and at the left cornu in the neighbourhood of the tube I could detect a small localized bulging. I told her husband of my fear that there might be an extrauterine pregnancy, and that I was chiefly alarmed because it was so close beside the uterus. My fear appeared to be fully justified when, two days later, a cast complete except at one corner was expelled. I thought I would have to open the abdomen at this stage, but my friend requested me to delay doing so. We were, however, prepared for any possible sudden call to operate; the patient was watched very carefully, and all discharges kept. Four days later a small piece of membrane, which just completed the sac that was expelled, came away in the vaginal discharge. Attached to this little piece of decidua was the ovum, which, unfortunately, I lost.

The two cases recorded above and the others I have encountered have all shown similar features: (1) pain; (2) lateral distension of the uterus in the region of the uterine cornu; and (3) tendency to abortion. The pain, as these recorded cases illustrate, may be very severe; indeed, in all the cases I have seen pain has been a pronounced feature. The reason for the pain can only be surmised. Round the tubal ostium there is a very abundant distribution of circular muscle fibres. Again, the blood supply is rich in that region, so that haemorrhages into the uterine wall or beneath the placenta are prone to occur. This is probably the explanation also of the tendency to abortion with this implantation. Of these six definite cases three terminated in abortion.

The outline of the uterine distension is characteristic: an elongated, distended lateral sacculation of the uterus at one cornu. Furthermore, it is very tender to pressure. In the case recapitulated the distension was no greater than the size of a walnut (examined under anaesthesia). In another case—an abortion at four months, which I removed with my fingers—I was afraid that I might perforate the uterine wall. From my experience the condition most commonly first attracts attention, as in the two cases here recorded, between the twelfth and twentieth weeks of pregnancy. It is obvious that the condition very closely simulates ectopic pregnancy,

pregnancy in a rudimentary horn, a fibromyoma undergoing degeneration, an ovarian cyst with torsion of the pedicle, appendicitis with lateral flexion of the uterus, or pyelitis complicating pregnancy.

Scattered through obstetric literature are references to angular pregnancy. Paul Bar, Howard Kelly, and I directed attention to it long years ago. Few obstetricians, however, appear to recognize the condition as a specific clinical entity. Modern textbooks, even those of considerable size, make little if any reference to it. For example, the subject is not mentioned in Williams's *Obstetrics*, and is only briefly referred to in the sixth edition of DeLee's textbook. Several examples of cornual and angular pregnancy have been described in foreign journals, but British literature appears to be singularly lacking in such references. The two cases here described and most carefully investigated by myself and my staff cannot be unique experiences. As previously stated, I have already encountered four exactly similar. Many other obstetricians must have dealt with cases of a like nature; we should feel grateful if they would furnish a summary of their observations.

ACUTE EPIDURAL SPINAL ABSCESS

BY

LEONARD ABRAHAMSON, M.D., F.R.C.P.I.

HONORARY PHYSICIAN, RICHMOND, WHITWORTH, AND HARDWICKE
HOSPITALS, DUBLIN

A. A. McCONNELL, F.R.C.S.I.

HONORARY SURGEON, RICHMOND, WHITWORTH, AND HARDWICKE
HOSPITALS, DUBLIN

AND

G. R. WILSON, L.R.C.P. AND S.I.

The epidural space lies between the dura mater and the periosteum lining the bony walls of the vertebral canal. Dandy,¹ writing in 1926, deprecates the lack of anatomical description in current textbooks, and discusses the appearances of the space in a cadaver. He attaches great importance to variations in size. Absent over the cervical enlargement, and nearly so over the lumbar swelling, the epidural space becomes deepest where the spinal cord or the mass of its roots is smallest—that is, in the upper dorsal and lower lumbar sections. According to this author the space exists only on the dorsal aspect of the dura, the ventral dura being closely applied to the bones of the vertebrae and their ligaments. The experience of one of us (A. A. McC.) suggests that in the thoracic region of the cord the ventral dura is less firmly adherent than elsewhere.

Pathology

The epidural space is occupied by a loose meshwork of areolar tissue, which, by virtue of a feeble blood supply, offers a favourable site for infection. Epidural spinal abscess, known also as suppurative peripachymeningitis, and by the more generic but less accurate term "external pachymeningitis," is an uncommon but important disease. Many of the recorded cases have been discovered at necropsy, and although there is a record by Traube as long ago as 1871 the condition occupies little or no space in the textbooks.

Dandy classifies the causes into two groups:

1. Extension from a neighbouring focus of infection—namely, boils, or anthrax of the nape of the neck; extrapleural suppuration; osteomyelitis of a rib; osteomyelitis of the vertebrae.
2. Metastatic infection from a distant source.

In a third group no primary focus can be detected. The infectious agent is most often the *Staphylococcus aureus*, though the *Staphylococcus albus* and other organisms may occasionally be found.

Owing to the looseness of the dorsal epidural space the abscess almost invariably lies posterior to the cord, except where it is secondary to disease of the vertebral bodies. For the same reason spread may occur with great rapidity. In a case described by Mixer and Smithwick² the abscess extended from the fourth cervical vertebra to the sacrum. These authors emphasize the danger of secondary meningitis in those cases in which a ventral abscess was associated with vertebral osteomyelitis: whilst present in two cases of ventral abscess it was absent in eight cases of dorsal abscess. Insistence is laid on the importance of early recognition and drainage of epidural abscess secondary to infection of vertebrae.

Compression of the spinal cord inevitably follows abscess formation, but the severity of the myelitis is out of all proportion to the amount of compression.

This is well borne out by reports of Hassin,³ and of Ayer and Viets.⁴ When examined at necropsy the cords were not badly compressed, but in section showed marked softening. To explain this finding Hassin suggests that substances from the epidural space may travel along the spinal roots. Allen and Kahn⁵ attribute cord softening to interference with blood supply.

Diagnosis

The diagnosis of epidural abscess may offer considerable difficulty. A survey of the literature reveals the fact that in most of the cases the diagnosis was either missed or was made too late for successful surgical intervention.

Dandy found that, of twenty-five collected cases, in only four subjected to operation was a diagnosis even suspected before the necropsy findings, and with the exception of one case there was no evidence to indicate that the nature of the lesion was more than roughly guessed. On the other hand, Bunch and Madden,⁶ in a later series of nineteen cases, including two of their own, report operative intervention in sixteen. In some of the reported cases a diagnosis was made of meningitis, in others of myelitis. Allen and Kahn offer as differential diagnosis: poliomyelitis, leptomeningitis, tumour of the cord, and abscess of the cord.

From the clinical aspect pain is the earliest and the most important symptom. It is severe and persistent, and is felt not only in the back, but along the distribution of nerve-roots, irradiating at times to the lower limbs. There is often a latent period, even up to several days, before motor symptoms appear. On the other hand, but rarely, paralysis may occur and reach completeness after some hours. Complaint may be made of stiffness and tenderness in the back and neck, with pain on movement. With the appearance of paralysis there is implication of the sphincters, with difficulty of micturition and defaecation. Disturbance of sensation may appear, and extend upwards. General septic symptoms vary in severity.

Röntgenological examination is not helpful, except in cases in which osteomyelitis of vertebrae has been present for some time. Lumbar puncture may show pus from the epidural abscess, or evidence of compression in the fluid from the subarachnoid space, and these help materially in diagnosis. That it is not an altogether innocuous procedure is shown by records of two cases in which it was followed by septic infection of the meninges. Careful technique should help to minimise, if not to eliminate, the risk. In cases in which neurological findings are inconclusive in regard to localization, recourse should be had to radiography following intracisternal introduction of lipiodol.

The mortality of epidural abscess in the untreated is, as far as published results go, 100 per cent. Of sixty

cases collected by us from the literature, operation was performed in thirty. Of these, twenty survived. In many cases recovery was incomplete.

Case Report

The patient, a schoolgirl aged 14 years, previously healthy, complained of vague pain in the back on July 28th, 1933. She appeared rather seedy and listless, but went about as usual. The pain increased steadily until the fifth day, when one of us (G. R. W.) was called in. The pain was described as severe, situated over both sacro-iliac joints, and radiating round the body at the level of the iliac crests. The most striking thing was the child's attitude. She was standing up and was suspending herself from the mother's shoulders. She said that this was the only position which gave relief. There was no limitation of movement, except that flexion of the neck hurt the lower part of the back. There was no tenderness over spine or pelvis. The tongue was furred. Temperature 99° F., pulse 104.

That night she complained of pain in the legs as well as in the back. The pain steadily increased, and was hardly modified by various drugs, including morphine. On the following day pain was persistent, eased somewhat by sitting in a chair. One of us (L. A.), called in consultation, suggested a diagnosis of osteomyelitis or periostitis of the spine. The next day there was complaint of pins and needles, mainly in the left leg. The day after this a second consultation was held. The patient was sitting up, and on getting back to bed for examination complained of a severe spasm of abdominal pain. Simultaneously, the lower abdominal muscles were seen to stiffen. Tendon reflexes were exaggerated in the lower limbs. Constipation was marked. A tentative diagnosis was made of epidural spinal abscess, probably secondary to an osteomyelitis. Arrangements were made for removal to a nursing home for full investigation. On the following morning, nine days after the onset of pain, numbness developed in both legs, with inability to move the right leg. Retention of urine was noted. The patient became very restless and occasionally delirious. Temperature 100.4° F., pulse 130, respirations 32. X-ray examination of the spine was negative, and, surgical treatment being considered advisable, one of us (A. A. McC.) was called in.

At this time—the early afternoon of August 5th—the patient complained of agonizing pain in her back and round her body, just below the umbilicus. She looked anxious; breathing was rapid and shallow. Tongue coated; colour good. She had free movement of head and neck, though flexion of the latter produced pain referred to the lumbar region. Abdominal reflexes were absent, with the exception of a slight upper left reflex. Slight tenderness was felt in lower dorsal and lumbar regions, described as "different from higher up." Left leg flaccid; could move great toe, flex ankle, and make an attempt to lift the leg. Plantar stimulation caused withdrawal and marked contraction of the hamstrings; no Babinski's sign. Knee-jerk and ankle-jerk absent. Right leg powerless and flaccid; there was just the slightest movement of the great toe. Stimulation of the sole produced the same response as on the left side. In both legs the sense of position was present. Sensation was normal except over the upper part of Scarpa's triangle on the left side, which was anaesthetic to cotton-wool and to pin-prick. Anal reflex present. Kernig's sign negative. The girdle pain, just below the level of the umbilicus, suggested a localization as high as the tenth dorsal segment of the cord, as did also the presence of an upper abdominal reflex, with absence of the lower reflexes. The anaesthesia in the upper part of Scarpa's triangle suggested involvement of the second lumbar nerve root.

Operation.—Lumbar puncture was done in the recumbent position, with local anaesthesia. When the spine was opened the patient complained of pain down both legs and all over them; no tension of fluid (50 mm. water); no change on lumbar compression; fluid slightly yellow. As a result of this absolute reliance on the patient's localization of the girdle pain and on the upper left spinal reflex was decided, lipiodol was introduced by sub-arachnoid puncture. Asepsis was maintained and anaesthesia completed with ether. Patient

grams, taken by Dr. McDonough, showed that the lipiodol was arrested at the level of the eighth dorsal vertebra. This confirmed the clinical localization, and the laminae of the eighth, ninth, and tenth dorsal vertebrae were therefore removed. Mr. A. Chance assisted. As soon as the ligamentum subflava was opened a gush of thick pus welled up, chiefly from the left side. When the dura pulsated freely the wound was drained, and partially closed. A posterior plaster case was applied. A pure culture of *Staphylococcus aureus* was grown from the pus, and a vaccine prepared.

Subsequent History.—On the day following the operation there was complete flaccid paraplegia, with total absence of response to all forms of stimulation. Sensation was unimpaired except over Scarpa's triangle on the left side. On the next day voluntary movement of the left great toe returned; stimulation of the sole produced slight movements of the toes. Painful flexor spasms occurred, chiefly in the left leg, and recurred periodically for seventeen days. Eleven days after the operation good movement was noted in the left leg at all joints. Knee-jerk and ankle-jerk present; slight ankle-clonus. Normal plantar response. No movement in right leg except slight movement of great toe. Knee-jerk and ankle-jerk exaggerated; ankle-clonus. No plantar response. Light touch present over both limbs. Sense of position of toes accurate in left foot, usually accurate in right foot. Sixteen days after the operation voluntary movement appeared in right leg, and improved from day to day, though there was no power yet to flex the hip or knee. Left leg movements were fairly good, but the patient made no attempt to move either leg unless told to do so. The temperature, which had oscillated at first between 100° and 103° F., gradually subsided in the third week, and the pulse rate, at first 120 to 130, descended to normal. The bladder condition remained unchanged. The wound looked clean, but discharged freely. The general condition improved, and toxic symptoms disappeared.

On September 3rd the patient began to pass urine at will. On October 1st the power of walking began to return. The gait was spastic. A month later she was able to walk about a quarter of a mile; gait slightly spastic; tendon-jerks slightly increased; transitory ankle-clonus. Shortly after this slight girdle pain returned at the level of the lower chest, disappearing in the erect position. This passed off following the extrusion of a spicule of bone from the sinus. Further progress was uneventful, and at the end of April, 1934, the patient is normal in every way.

Summary

We present a case of epidural spinal abscess in which recovery followed a surgical operation. The interesting features of the case were as follows:

1. The intensity of the pain, which at its height defied all drugs, including morphine.
2. The radiation of pain round the trunk.
3. The relief afforded by the adoption of an attitude which relaxed the spine.
4. The evidence of anterior root irritation, as shown by sudden stiffening of abdominal muscles.
5. The almost complete absence of anaesthesia.
6. The latent period of eight to nine days which preceded paralysis.
7. The fact that adequate drainage was secured by the removal of three laminae. Operations on a much more extensive scale are described in the literature.

Our experience with this case suggests that removal of a large number of laminae is unnecessary. This is of obvious importance in regard to operative risk.

TETANUS IN TOY-PISTOL WOUNDS

BY

WILLIAM BROWN, M.D.

ASSISTANT SURGEON TO OUT-PATIENTS, GLASGOW ROYAL INFIRMARY

The prophylactic use of antitetanic serum has proved so useful in cases where infection is suspected that the following case, illustrating a rare mode of infection, is worthy of notice so that early treatment on prophylactic lines can be instituted and a probable catastrophe prevented.

Case Record

An otherwise healthy boy of 8 was admitted to the Glasgow Royal Infirmary on December 9th, 1933, suffering from tetanus. The following history was obtained.

On December 2nd, 1933, he was playing with a toy pistol and some blank cartridges, for which he had exchanged a magic lantern with another boy. The pistol went off unexpectedly, and he sustained a wound of his left index finger, for which he was treated at home by his mother. On December 9th, seven days later, he developed stiffness of his jaws, and the family doctor was called in. He diagnosed tetanus, and sent him into the Royal Infirmary at once.

On admission there was well-marked trismus, associated with tenseness of the neck and back. There was also slight head retraction. He could open his mouth half an inch. He had slight convulsions, associated with some degree of opisthotonos. The left index finger was seen to have a septic wound at the base.

The boy was put into a side room with the blinds drawn and antitetanic serum administered at once. His condition gradually became worse, and on the third day the left index finger was amputated. He died quite suddenly the following day.

Serum Treatment.—On admission he was given 40,000 units of antitetanic serum intramuscularly and 20,000 units intrathecally. Next day he was given 120,000 units intramuscularly and 80,000 units intrathecally. On December 11th he had 10,000 units intramuscularly, and on the 12th 12,000 units intramuscularly and 40,000 units intrathecally. On the 13th he was given 80,000 units intrathecally.

The cerebro-spinal fluid showed nothing on culture or smear. No cultures were taken from the wound on the finger either before or after amputation.

In an endeavour to discover the source of infection I obtained from the procurator-fiscal one of the two remaining cartridges. The police were unable to trace where the cartridges were bought. However, I managed to buy some of a similar make in a shop. The original cartridge and some of the bought ones I gave to Dr. Robert Cruickshank, bacteriologist to the Glasgow Royal Infirmary. Others I sent to Dr. Clark Trotter, medical officer of health for Islington, at his own request, and he had them examined by Professor James McIntosh, director of the Bland-Sutton Institute, Middlesex Hospital. Professor McIntosh reports as follows:

"The wads were made of a rough type of paper. The cultures grew staphylococci, streptococci, coliform bacilli, and diphtheroid bacilli. No *Bacilli tetani* grew."

Dr. Cruickshank reports as follows:

"None of the bullets examined bacteriologically gave a growth of *B. tetani* either by cultural methods or by pathogenicity tests, nor were there organisms of an associated nature, such as *B. sporogenes*, which would have suggested the possible presence of *B. tetani*. The organisms recovered were aerobic and spore-bearing bacteria such as might be found in dust and in the atmosphere. On physical examination of the cartridges there was no evidence of any material—for example, horse-hair felt—likely to harbour *B. tetani*."

Tetanus infection from blank cartridge wounds has not received much attention in this country, although it has been known for some time in the United States, where

it was common following the celebrations of Independence Day on July 4th. In America,¹ in 1903, despite official warnings, over 400 patients died from tetanus due to this cause alone. The incubation period was short and the disease very virulent. In the majority of cases the wounds were in the hands. Recommendations were made regarding the sale of toy pistols and blank cartridges and the giving of antitetanic serum in all wounds of this nature. This reduced the mortality to three in the 1914 Independence Day celebrations.

Miss Smith² reported four cases with three deaths, occurring in London in 1932. The wadding of the blank cartridges was examined for *B. tetani*, but none were found. However, other anaerobes were isolated, particularly *B. sporogenes*. She points out that this does not exclude *B. tetani*, as it is difficult to isolate *B. tetani* from mixed company. In America, following the 1903 cases, a large number of blank cartridges were examined, but in no case was *B. tetani* found, although one culture, inoculated into rats, caused death from convulsions. Other instances of death from tetanus associated with toy-pistol wounds were reported by Stokes,³ Schofield,⁴ and Clark Trotter.^{5,6} In Dr. Clark Trotter's case the cartridges were examined by Professor McIntosh, and *B. tetani* was found. It was observed then that only in those cartridges with a wad containing hair felt was the organism obtained. Dr. Clark Trotter remarks that thorough sterilization, before being used as a wad, is the only certain way of preventing these accidents.

There is, of course, no direct evidence that the tetanus infection in this case was derived from the cartridge, but the frequency of tetanus after wounds due to the use of toy pistols and blank cartridges suggests that either the infecting organisms were already present in the cartridge or that the type of wound, associated with mild sepsis, may predispose to tetanus infection. The rarity of tetanus seen at the out-patient department of a large hospital, such as the Glasgow Royal Infirmary, which deals with a very large number of street accidents, would suggest that either of these two reasons is correct. It is important that the general public and the medical profession should be aware of this possible danger from toy-pistol wounds, so that early treatment can be given, as, once the disease is established, the prognosis is well-nigh hopeless.

I am indebted to Mr. Dunbar of the Glasgow Royal Infirmary for allowing me to publish this case, and to Professor McIntosh and Dr. Cruickshank for the bacteriological examinations, and also to Dr. Clark Trotter for sending me a copy of his annual report.

THE TREATMENT OF PNEUMOCOCCAL EMPYEMA WITH BILE SALTS

BY

B. R. SWORN, F.R.C.S.

HONORARY ASSISTANT SURGEON, STAFFORDSHIRE GENERAL INFIRMARY
AND

T. V. COOPER, M.B., B.S.

ASSISTANT BACTERIOLOGIST, STAFFORDSHIRE COUNTY COUNCIL

The lysis of pneumococci by bile was noted by Neufeld¹ over thirty years ago, and Levy² in 1907 proposed its use as a differential test between pneumococci and streptococci of the *viridans* group. Many workers have sought for a chemotherapeutic agent in the treatment of pneumococcal infections—notably Lamar,³ Morgenroth and Levy,⁴ and Felton.⁵ Cocchi⁶ in Italy and Thomson⁷ in this country have described the treatment of pneumococcal empyema by aspiration of the pus followed by the injection of a solution of sodium taurocholate. This method appeared to offer so many advantages that we decided to try it, and in our first cases we used the 20 per cent. solution of sodium taurocholate recommended by Cocchi.

It has been customary for some years in this laboratory to add 0.1 c.cm. of a 10 per cent. solution of sodium desoxycholate to 5 c.cm. of broth culture (brought to pH 7.8) as a test for pneumococci. Lysis should occur within five minutes. This modification of the classical test was made following the suggestion of Mair,⁸ and laboratory experience of the varying potency of individual samples of commercial sodium taurocholate. In addition, there is the advantage of using a substance which is chemically pure. We accordingly decided to try this salt clinically.

Before doing this we made *in vitro* experiments to compare the lytic potency of the sodium taurocholate in use with that of sodium desoxycholate. A thirty-hour broth culture of the strain of Type I pneumococci, recovered from one of the cases undergoing treatment,

was used. Before adding the substances under test the broth reaction was adjusted to pH 7.8. It was found that whereas 0.2 gram of sodium taurocholate (1 c.cm. of a 20 per cent. solution) was required to produce lysis in 5 c.cm. of the broth culture, 0.0125 gram (0.25 c.cm. of a 5 per cent. solution) of sodium desoxycholate achieved the same result—that is, the sodium desoxycholate is sixteen times more potent.

We endeavoured to assess the toxicity of the desoxycholate by animal experiment. Three 250-gram guinea-pigs were taken. The first received 1 c.cm. of a 10 per cent. solution intraperitoneally, and death occurred in twelve hours. The post-mortem revealed intestinal necrosis with haemolysis. The second received 1 c.cm. of a 2.5 per cent. solution intraperitoneally with no observable ill effect, while the third received 1 c.cm. of a 10 per cent. solution intramuscularly into the thigh and survived. We realized also that absorption might produce severe haemolysis, for *in vitro* experiments showed that it is over a hundred times more haemolytic for washed sheep's red corpuscles (fragility 0.65-0.5) than sodium taurocholate. For these reasons we have not injected sodium desoxycholate into an empyema until the presence of frank pus shows that a definite abscess cavity has formed.

Method of Use and Results

The technique of the treatment of empyema by the injection method is simple. The presence of pneumococci in the pus must first be confirmed, since it is only on these organisms that lysis takes place. The abscess cavity is then aspirated again, and as much pus as possible drawn off. With the needle still in position the solution of sodium desoxycholate is injected, and we have used from 5 to 20 c.cm. of a 5 per cent. solution of the salt.

The best results seem to be obtained by repeating the aspiration and injection daily, or every other day, in the early stages, but the length of time that can be

allowed to elapse can be gauged by the general condition of the patient, the amount of pus withdrawn, and the results of microscopical examination and culture of the pus. We have found radiograms of the chest of considerable assistance in estimating the quantity of fluid present. It is essential that strict surgical asepsis must be maintained, as it is very easy to introduce secondary organisms where frequent aspiration is being undertaken, and if this occurs it will, of course, necessitate the institution of continuous drainage. The use of a trocar and cannula has been advocated for puncture of the chest wall in order to prevent the carriage of a punched-out portion of skin by an exploring needle, but we have not found this necessary. In a favourable case the temperature rapidly falls, the general condition of the patient improves, and the pus becomes thinner. In some cases the salt tends to jellyfy, particularly where relatively large quantities of the solution are injected into a small quantity of pus, but we have not found that this has interfered materially with aspiration.

Cocchi has suggested that the bile salts, besides causing lysis of the organisms, may have some action in producing liquefaction of the fibrin, which is usually formed in such large amounts in the pleural cavity. Certainly we have never found the needle to block during the aspiration, and at the end of treatment the clinical signs and clearness of the chest to x rays indicate a small degree of pleural thickening. The latter is, however, probably due partly to the avoidance of secondary infection and the absence of irritation caused by a drainage tube. Examination of the pus during the course of treatment showed characteristic changes. At the commencement microscopy revealed 95 per cent. polymorphonuclear pus, with the field crowded with diplococci. The first change noted was a marked reduction in the number of organisms and disintegration of the cellular constituents. Finally, the aspirated material consisted of amorphous debris with no intact organisms, but revealing occasional swollen cocci on prolonged search. Under these circumstances cultures were negative.

Although we have only had the opportunity of employing sodium desoxycholate in two cases it seems to offer both practical and theoretical advantages over sodium taurocholate, and in view of this we feel justified in bringing it forward in the hope that it may be subjected to a more extended clinical trial than we are able to give.

Case Records

Case 1.—M. E., aged 4½. Admitted January 9th, 1934, with signs of a left-sided empyema following pneumonia. Temperature 101–102° F., pulse 130–146. Chest aspirated, and 80 c.cm. of purulent fluid withdrawn. Culture showed pneumococci Type I. On January 12th 45 c.cm. of thick pus removed; 5 c.cm. of 20 per cent. sodium taurocholate injected. Aspiration and injection repeated daily, and by the 17th the temperature was normal, pulse 80–100, and the pus thin and sterile on culture. The frequency of aspiration was reduced. On February 2nd 200 c.cm. was withdrawn, and culture showed numerous pneumococci. Two days later, although the general condition remained satisfactory, the temperature began to rise, and ranged from 99° to 100° in the evenings, and the pulse varied between 100 and 120. It was about this time that we started a fresh batch of taurocholate, but the exact date is uncertain. This taurocholate was tested against cultures of the organism, and gave apparently satisfactory results. The boy continued to have an evening rise of temperature, and rather rapid pulse throughout the month of February, but his general condition remained surprisingly good. The pus withdrawn was rather thicker again, and pneumococci were usually grown on culture. On March 3rd we decided to try injections of sodium desoxycholate, and he was given 10 c.cm. of a 5 per cent. solution. The temperature was normal on the evening of the 5th (two days later), and did not again rise above

the line. The pulse rate fell, to reach normal a few days later. The amount of fluid on aspiration rapidly decreased, and was sterile on culture. Treatment was stopped on March 15th, but a week later a few cubic centimetres of serous fluid were withdrawn. He was discharged on March 17th, and a radiogram at this time showed a practically clear left base. He was seen after a month's interval, and had remained perfectly fit.

Case 2.—H. T., aged 15. Admitted March 18th, 1934, three weeks after the onset of pneumonia, with signs of right-sided empyema. Very cyanosed and toxic. Temperature ranging between 101° and 103° and pulse 120–130. On aspiration 23 oz. of pus were removed. Culture showed pure growth of pneumococci Type I. On March 19th 12 oz. of pus were removed and 10 c.cm. of sodium desoxycholate injected. The aspiration and injection was repeated every second day, and although the amount of pus withdrawn fell in about a week to 50–60 c.cm., he had all the signs of a solid right lung, and the temperature persisted between 99° and 100°. There had been complete absence of sputum during the course of the pneumonia, but he now began to bring up fairly large quantities of thick, muco-purulent sputum, which contained abundant pneumococci. We decided the condition was one of unresolved pneumonia, and that the pleural cavity was being continually reinfected from the underlying lung. In view of this, and as his general condition was much improved, we attempted to keep the empyema under control by repeating the aspiration and injection every few days, and the amount of pus drawn off varied from 10 to 60 c.cm. Although the direct smear showed a greatly reduced number of organisms the culture remained positive. He was given the usual medical treatment, and the signs in the right lung cleared very slowly. Coincident with this the sputum decreased and the temperature returned to normal. By April 26th the right lung seemed sufficiently normal to suggest that the empyema might remain sterile. The cavity was aspirated, and 15 c.cm. of 5 per cent. desoxycholate injected daily for four days. The temperature remained normal, and the cultures became sterile. On the last aspiration, on the 29th, only a few cubic centimetres of fluid were withdrawn.

In view of the fact that simple aspiration alone will sometimes cure a pneumococcal empyema in children it seems worth while to record the case of an adult treated by aspiration and injection of bile salts.

Case 3.—A. P., aged 21. Admitted January 15th, 1934, with signs of left-sided empyema following pneumonia. General condition very poor. Temperature 101°, pulse 120. On aspiration 200 c.cm. of straw-coloured fluid was removed. Abundant organisms seen on smears. Culture: pneumococci Type I. January 20th: On aspiration 350 c.cm. of pus was obtained, and 10 c.cm. of 20 per cent. sodium taurocholate injected. January 22nd: jelly-like pus was aspirated (30 c.cm.), and 10 c.cm. of taurocholate injected. The temperature was now normal, and smears of the pus showed no organisms, although a few pneumococci were grown. January 23rd: brownish fluid was aspirated (250 c.cm.), and 10 c.cm. of taurocholate injected. Temperature normal and cultures sterile. January 25th: 100 c.cm. of blood-stained fluid was withdrawn. No injection was given. Cultures of this fluid were sterile. The patient was aspirated on two subsequent occasions, and a small quantity of sterile fluid was withdrawn. Radiograms at this time showed "unexpanded lung left base." He was discharged on February 11th, and seen again four weeks later, when he was quite well, and a radiogram showed the left lung practically clear.

We wish to thank Dr. John Menton, county bacteriologist, for his advice and assistance.

Clinical Memoranda

VOLVULUS OF THE CAECUM COMPLICATING LABOUR

This case is interesting owing to its rarity and the difficulties to which it gave rise in diagnosis.

A primipara, aged 23, about thirty-eight weeks pregnant, and with slight pelvic contraction, was admitted to the Mothers' Hospital, Clapton, at 11 p.m. on November 14th, 1933; suffering from abdominal pains, which she thought were the beginning of labour. The pain was most marked under the right costal margin, and was sometimes colicky in nature and sometimes continuous. Uterine contractions could be felt, and she was thought to be in labour. The note "pains good" appears on her chart for that night.

Owing to the unusual nature of the pain, she was seen next morning by the senior honorary obstetric surgeon, who did not consider there was any immediate indication for interfering with the course of labour, but advised that she should be carefully watched. The condition remained more or less the same until the following morning, but the abdomen was noticed to be getting more distended. Vomiting was present, but not to a greater extent than may occur during uncomplicated labour, and the vomited material was a clear fluid. The bowels did not act, and there was no result to an enema.

I saw the patient for the first time at 1 p.m. on November 16th, and I thought then that her condition suggested a pulmonary lesion, or possibly an obscure toxæmia, rather than an acute abdomen. She had been dyspnoeic since the early morning, and looked drowsy and somewhat cyanosed. Her temperature was 100°, her pulse 120, and her respirations 28. She resented abdominal examination, but there was no obvious resistance, and there was a conspicuous lack of tenderness on pelvic examination. The head was high and the cervix undilated. The patient was seen at 5 p.m. by the consulting physician, who considered the signs in the chest were due to collapse of the lung from increased intra-abdominal pressure rather than to a primary pulmonary lesion, and advised laparotomy. It was also felt that a Caesarean section would be the safest method of delivery in view of the patient's condition.

I operated at 9 p.m., there having been no result to further enemata. A little turbid fluid escaped on opening the abdomen, but it was impossible to trace its origin until the uterus had been emptied by Caesarean section. With the hope of lessening the risk of infection here, the uterus was everted and painted with violet-green before being incised, and was swabbed out with it before being sutured. A volvulus of the caecum was found, the caecum being enormously distended. Its walls were deep purple in parts, and showed areas of superficial necrosis where the peritoneal coat had split. A Meckel's diverticulum was present, looking like a tightly blown-up finger of a rubber glove. The volvulus was untwisted without difficulty, and any doubtful areas of the caecum were oversewn. The abdomen was closed without drainage, a caecostomy being performed.

The patient made very satisfactory progress for the first five or six days, although she had a rapid pulse. After this, however, her temperature became irregular, and finally she developed a cystic swelling on the left side of the abdomen. On December 8th I operated again, and drained a large pelvic abscess, well shut off by adhesions, the pus lying partly in front of and partly behind the uterus. The left tube and ovary were more or less disintegrated, the greater part of the tube having sloughed off the uterus. The right tube and ovary were inflamed but seemed recoverable, and were left *in situ*. The patient ultimately did well, and was discharged cured with a healthy baby on February 2nd, 1934. The caecostomy wound had still not healed, owing to the development of a large polypus, which I shall remove later if necessary. Her convalescence was delayed by a *B. coli* infection of the urinary tract, and also by the original wound breaking down.

Since writing in the above report I have had the patient back in hospital to excise and close the caecostomy wound. The polyp proved to be a polypoid diverticulum of the right Fallopian tube (confirmed by microscopical examination).

The fimbriated end of the tube was closed. The ovary had regained its normal appearance. I removed the polyp and did a salpingostomy, and an inflation test three weeks later showed that the opening had remained patent.

This case illustrates the difficulty that may be met in diagnosing an acute abdominal condition when it occurs during labour (it is well known that the symptoms of acute appendicitis occurring then may be almost completely masked), and it bears out the maxim that where there is any reason to suspect such a condition then, or during pregnancy or the puerperium, it is much safer to do a laparotomy, even should the operation prove to be unnecessary. By far the most striking symptom in this case was the intense dyspnoea, which finally became so marked that the patient could hardly bear to be moved.

MARGARET M. BASDEN, M.D.,

F.R.C.S., F.C.O.G.

Obstetric Surgeon, Mothers' Hospital, Clapton.

CARCINOMA OF THE APPENDIX

This case is published as a plea for the routine examination of every appendix removed, whether it looks diseased or not.

A single woman of 35 years, well nourished, was admitted on account of abdominal pain and vomiting; the temperature and pulse were normal, the abdomen resistant in the right iliac fossa but not rigid; there was a history of chronic constipation.

A laparotomy was performed and the abdominal viscera examined and found to be normal; a perfectly normal-looking appendix was removed. After operation the appendix was slit up along the lumen, and this was possible except for the last quarter of an inch at the tip; the section was completed from the outside.

The above diagram shows the appendix in sagittal section; the growth at the distal end did not interfere with the contour of the appendix, and felt rather like a faecolith; on cutting, there was a gritty sensation on contact with the scalpel. The patient made an uninterrupted recovery.

The microscopical report was as follows: "The section shows a carcinoma which is infiltrating the muscle and sub-mucous coats of the appendix. There is some alveolar formation, but no lumina can be seen. In other places the cells are arranged in large masses. Most of the cells are tending to a columnar type, and are producing globules of mucus. This growth probably arose from appendicular mucous membrane, and does not appear to be very malignant."

Two months later the patient again presented herself, complaining of constipation, swelling of the abdomen, and vomiting, rather suggestive of obstruction. Immediate laparotomy was carried out; it was found that a knuckle of small intestine had gone into a retroperitoneal fossa behind the caecum. This was released, and she made a good recovery. At this operation a careful survey of the abdominal cavity was made; there were no enlarged glands, and no secondaries in the liver or on the peritoneum. She has been seen at intervals during the past six months, and apart from her habitual constipation remains well; her abdomen is flat and soft.

The point debated in regard to after-treatment was: should the patient have a course of deep x-ray therapy? This was decided against, chiefly because the patient might become aware of the nature of her complaint and give it an undue significance, and because of the good prognosis in similar cases.

H.M.S. 246, London.

Reviews

FASCICULUS CESTRIENSIS

From time to time, outside the ranks of consulting practitioners, there arise in this country men who by their intrinsic merit and character become in the course of years masters of medicine to their colleagues, and stand in the position of father in a professional sense to the doctors of a wide area. In the publication of *Fasciculus Cestriensis*¹ the doctors of the county of Cheshire, through the Panel Committee, seek to pay tribute to such a man in the person of Sir William Hodgson, who having just celebrated his eightieth birthday still presides as chairman over the Panel Committee and County Council of Cheshire.

In its manner and content this book adopts a new and original method. The first portion is concerned with a biographical sketch of Sir William Hodgson's public and professional life. After a childhood of by no means uneventful changes, we follow his student career at St. Thomas's Hospital, and Glasgow, Edinburgh, and Dublin, under the influence of men such as Barnes and Lister, to the field of general practice, which to him seemed to open the widest door to the many-sided interests of his knowledge and abilities. Soon after starting practice in Crewe we find him deeply immersed in local political and industrial problems. These controversies gave early proof of his powers as an organizer and fighter, and introduced a new force and spirit both in the council chamber and in the big industrial organizations of the district.

The establishment of county councils in 1889 and his election as member for Crewe widened his sphere of usefulness in public affairs and opened fresh fields for the forceful pursuit of his ideals. Mayor of Crewe in 1892, and later chairman of the Licensing Justices, no side of public life failed to feel his influence and profit by his wide knowledge of human affairs. As champion of the local profession in the bitter controversy associated with the establishment of national health insurance he set the seal on his popularity with the doctors of the county. In recognition of his long and arduous public services he was knighted in 1920, and seven years later the Freedom of Crewe was conferred upon him on the occasion of the jubilee of the incorporation of the borough.

Such is a brief sketch of the biography here set out, which must leave two impressions in particular on the minds of those who read the full narrative. First, the wonder that one man, none too robust in health, should find time to accomplish so much in a lifetime. To establish and maintain a large practice, to take part in sport and recreation in addition to this large share in public life, might well seem impossible to most men. Here is a lesson in the value of time, and one more example of the truth of the saying that it is the busy man who has time to do things. The other impression is a reminder that in all the complicated organization of public affairs, with its committees, councils, and the like, we must look to the individual to supply the driving force. However big the machine the man with certain qualities will never fail to make his influence felt.

It is in the second portion of this book that a new feature is presented. There is added a sheaf of clinical memoranda compiled by fifty and more Cheshire doctors. These are intended to provide a record of the state of medicine in the county at the present time, a state which Sir William has done so much to foster. The

monographs vary in length and quality from a full article on a given subject based on specialist study to the merest clinical note, and all are readable.

The whole book is a striking local tribute to an outstanding member of the profession. It will claim attention outside the county of Cheshire, and we congratulate those responsible for its production.

ABDOMINAL DIAGNOSIS

Les Diagnostics Chirurgicaux au Lit du Malade,² by M. BARTHÉLEMY, deals entirely with problems of abdominal diagnosis, discussing them purely from a practical standpoint. It is intended for advanced students, and especially for those who are already engaged in practice. It is illustrated by descriptions of cases which have occurred in the author's practice, and, indeed, it closely resembles the running commentary which a surgeon is accustomed to give when taking his students round the hospital wards. It commences with a discussion on abdominal wounds and injuries, followed by some considerations regarding hernia. The complications of gastric ulcer, hæmorrhage, perforation, and subphrenic abscess are discussed in very brief terms, and a few more pages are given to stenosis of the pylorus. Affections of the biliary passages and the pancreas are discussed at somewhat greater length, as are also the clinical forms of appendicitis. Chapters following on cancer of the colon and affections of the rectum complete the first part of the work. The whole of the second part is devoted to gynaecology, so that this subject is dealt with in far greater detail than is general surgery. The fact that nearly a quarter of the text is devoted to affections of the uterus indicates very clearly the predilection of the author.

An attractive feature of the book is the series of rough sketches by which it is illustrated. Although very rough, and in some cases even crude, they indicate most clearly the intention of the author, and are probably of greater practical value than more carefully executed drawings. We can imagine that the book will be of real value to many surgeons who are working on their own away from the larger centres, and especially to those who have to deal with the more pressing emergencies of gynaecology.

SEX TEACHING

A small book by THEODORE F. TUCKER and MURIEL POUT, entitled *Awkward Questions of Childhood*,³ will be found a help to many parents and teachers. The experience of the authors, as evidenced by this and a previous book on *Sex Education in Schools*, has mainly been with elementary school children; and this experience, together with a considerable period of experimental talks and teaching, entitles what they say to be received with respect and to be regarded as having some authority, as founded upon a practical basis and designed to meet real requirements. The book consists of an introductory chapter on "Some Principles of Sex Education," a number of answers to specific questions which are commonly asked by children of various ages, and two supplementary chapters dealing respectively with the subjects of masturbation and adolescent friendships. Each of the answers suggested in the main portion of the book is followed by a section giving to parents and teachers some reasons for the answers recommended, together with additional information

¹ *Les Diagnostics Chirurgicaux au Lit du Malade*. Par M. Barthélemy. Paris: N. Maloine. 1933. (Pp. 306; 101 figures. 45 fr.)

² *Fasciculus Cestriensis in Honour of Sir William Hodgson*. Issued on the occasion of his eightieth birthday, May 13th, 1934. Copies will be on sale at 15s.

³ *Awkward Questions of Childhood. A Practical Handbook on Sex Education for Parents and Teachers*. By Theodore F. Tucker and Muriel Pout, B.Sc. London: Gerald Howe, Ltd. 1934. (Pp. 162. 3s. 6d. net.)

relevant thereto, such as may enable them to appreciate more fully the nature of those answers, and perhaps help them also to meet any supplementary questions. It is recognized, of course, that not every question will be asked by every child; indeed, it is probable that some of them are asked by very few children. The authors, however, give a place not only to the universal "Where do babies come from?" but to the occasional "What is birth control?" or "What are venereal diseases?" The answers set out are for the most part wise and sufficient. Parents and teachers will be advantaged, not necessarily by adopting them, but at least by considering them. There is some tendency to prolixity and undue repetition, especially in the introductory chapter and in a few of the sections for those who give the answers. And it may be doubted whether there is any great value in the two answers which introduce to the boy or girl the mention of chromosomes. This can scarcely be effective except in the course of some regular instruction in general biology. So also doubt may be expressed as to the wisdom of the suggestion that the unwanted child should always be avoided, and of the statement or implication that deaf-mutism is always directly inherited. Of the general value of the book, however, there can be no doubt; and its emphasis on the importance of positive teaching and frank answering, as contrasted with avoidance, prohibition, and negation, is fundamental.

THE LAW OF INDUSTRIAL DISEASES

Doctors and lawyers concerned with administering the Workmen's Compensation Acts have to face a difficult task in applying the numerous sections, schedules, appendices, regulations, and decisions which contain the law relating to industrial diseases. Several good textbooks have been written on the Act itself, but many practitioners—in particular, medical referees and certifying surgeons—need a fuller explanation of this particular aspect. Mr. C. H. SPAFFORD has taken Sections 43 and 44 and written a very clear and concise commentary⁴ on them, and has considered the effect of the most recent decisions by the Court of Appeal and the House of Lords. He devotes a chapter to the certificate of disablement, its contents, the conditions under which it is conclusive, and the remedies available when it is defective. The appeal to the medical referee is fully discussed, and legal readers will find the chapters on determining the employer who is primarily liable, and the joinder of previous employers, of great practical value. As a book of reference the volume has considerable advantages over the existing textbooks because of its clarity and orderly arrangement. The only criticism that can fairly be made is in respect of the price, which seems very high for a small octavo volume.

A SHORT HISTORY OF MEDICAL SCIENCE

Dr. G. B. GRUBER, professor of pathology in the University of Göttingen, has published, under the title "An Introduction to the Spirit and Study of Medicine,"⁵ an interesting course of lectures delivered to students commencing their medical education. They comprise a short explanation of the manner in which medicine advanced to its present position.

The first lecture gives a general review of the development of biological science up to the time of Galen. The

succeeding fifteen hundred years are barely noted, and the second lecture deals with Vesalius—his work and its consequences. Subsequent lectures deal in turn with the development of the medical sciences. Thus the history of the fundamental sciences of histology, physiology, psychology, and genetics is treated first, to be followed by an account of such applied sciences as pathology, bacteriology, pharmacology, and hygiene. The final papers are devoted to a consideration of the relations between the medical profession and the rest of society. The subjects discussed under the last heading include the cloud of cults and quack systems which compete with modern medical science by pandering to primitive superstitions; the medico-legal obligations of doctors; and matters bearing upon medical ethics.

The volume is a small one of about 250 pages, but within this compass the author provides a very readable survey of the wide range of topics upon which he touches. The general conception and purpose of the work seem excellent. The evolution of modern medicine, and in particular its spectacular growth during the past century, is not only a study of great general interest, but also one with which all medical students ought to have an acquaintance. From time to time we hear, a complaint that medical history is tending to lose its way in masses of personal detail about the careers and discoveries of great men. However that may be, there is ample room for general surveys such as Dr. Gruber gives here, providing a picture of the development of scientific ideas.

THE PATIENT'S CONSTITUTION

The medical practitioner is continually confronted with the problem of bodily constitution in the treatment of his patients, and he gets very little help in this matter from medical textbooks. The subject is treated inadequately, for the sufficient reason that the factors which determine individual constitution are extremely complex, and have only in recent years received satisfactory analysis. A very useful book has been issued by Professor NÄGELI under the title of "The General Doctrine of the Constitution,"⁶ providing a lucid account of what is known on the subject at the present time, with special reference to its bearing on medicine. It is deserving of careful study by medical practitioners. The problem of constitutional differences is one of "variability," and as the latter has been elucidated almost exclusively in the sciences of botany and zoology the medical man needs to revive his interest somewhat in those subjects in order to understand the doctrine. The author has for some years endeavoured in his lectures to merge medical science in the larger conception of natural history, and the present work is written apparently with a similar intent.

After discussing the definition of "constitution," the author enters in detail into the kinds and causes of variability, giving examples in botany, zoology, and man. Then follow special articles on hybridization, germinal induction, the hereditary transmission of acquired characters, race and constitution, and the influence of sex and age. The final chapters deal with the constitution and special diseases—namely, tuberculosis, pernicious anaemia, haemophilia, chlorosis, and the psychoneuroses. Apart from its bearing on medicine, the work will appeal strongly to all who are concerned with such subjects as evolution, palaeontology, and racial differences; and to the general reader from its inherent interest. Probably there is no other book in which the subject is so fully and clearly explained.

Notes on Books

The tenth edition of the late Professor CUSHNY'S *Text-book of Pharmacology and Therapeutics*¹ has been prepared by Professors C. W. EDMUNDS and J. A. GUNN. These authors undertook the difficult task of continuing the textbook eight years ago, and were responsible for the ninth edition, which appeared in 1928. Their general aim has been to preserve not merely the critical spirit of the book, but also the text as far as this is possible. Recent advances in pharmacology have, however, necessitated the rewriting of many sections, such, for example, as those on iron, bismuth, liver extract, and the barbiturates. In general, the whole volume has been carefully revised and brought up to date, but its size has only been increased by forty pages. The editors are to be congratulated on the skill and care they have expended in bringing the textbook up to date whilst preserving its characteristic form.

*Individual Psychology and Practice*² includes four contributions written by clinicians associated with the Adlerian movement. Dr. C. M. Bevan discusses the relationship between medicine and psychology, stressing especially the desirability of attempting some degree of integration between the various schools of dynamic psychology with a view to forming a liaison society between official medicine and general psychological thought. Dr. H. O. Woodcock writes on "The Tyranny of the Invalid"; Dr. F. A. Leighton on "The Purpose and Some Neuroses"; and Dr. F. Marjory Edwards discusses "The Psychological Approach to Gynaecological Problems." These clinical studies usefully exemplify the therapeutic aims and methods of the Adlerian school.

To one of the many series of short monographs now appearing in France, this one being entitled "New Therapeutics," Dr. F. RATHERY has contributed a modest booklet of fifty pages on "The Treatment of Juvenile Albuminuria." This subject requires a discussion of the causation of albumin in the urine, and leads to a diversity of methods, involving diet, hydrotherapy, and drugs, according to the many different diseases of which this condition is a symptom. The best sections are those on the treatment of albuminuria due to acute nephritis, and on orthostatic albuminuria, which opens with the wise remark, "In reality orthostatism favours the accentuation of all albuminuria."

*Metabolism Problems*³ is a small volume in which are printed a series of addresses given at the opening of the Summer University at Santander, by Professor S. J. THANNHAUSER of Freiburg. He deals with the following subjects: purine metabolism, the chemistry of the pigments of the blood and the bile; the site of formation of bile pigment; the causation of jaundice and disorders of cholesterol metabolism. All of these are difficult subjects, and in most of them knowledge is advancing somewhat slowly. The author gives a clear picture of the present state of knowledge, and in particular explains fully the chemical relationships of the complex substances whose fate he discusses. For example, he points out curious relationships between adenosine phosphate and the digitalis glucosides, both of which have the common property of exerting a selective action on heart muscle. The subject of chemical pathology is naturally difficult because the chemical substances which are studied are mostly of an exceptional complexity, but the author gives a very clear and interesting account of the problems which he considers.

¹ *A Textbook of Pharmacology and Therapeutics, or the Action of Drugs in Health and Disease.* By the late Arthur R. Cushny, M.A., M.D., LL.D., F.R.S. Tenth edition, thoroughly revised by C. W. Edmunds, A.B., M.D., and J. A. Gunn, M.A., M.D., D.Sc. London: J. and A. Churchill, Ltd. 1934 (Pp. 786; 75 figures. 25s.)

The richly documented monograph on Angina Pectoris¹¹ by Dr. GREGORIO N. MARTINEZ, professor of clinical medicine at Cordoba in the Argentine Republic, contains a full and up-to-date account of the history, aetiology, pathogenesis, symptomatology, diagnosis, prognosis, and treatment of the condition, with a record of forty-nine personal cases in patients aged from 16 to 74, illustrated by electrocardiograms. A bibliography of 652 references, in which British literature is well represented, is appended.

*Keith Lucas*¹² is an outline, but in some ways quite as pleasing as a full-dress edition, of a projected memoir of a physiologist of outstanding ability who lost his life in an aeroplane accident in 1916 when 37 years old. The late Sir Walter Fletcher had collected eight appreciations of various phases of Keith Lucas's life from his friends, and had written two accounts of him as an undergraduate and as a Fellow of Trinity College, Cambridge. Professor E. D. Adrian, the pupil and colleague, who in 1917 edited Keith Lucas's Page May Lecture (1914) on "The Conduction of the Nervous Impulse" (vide review in these columns, 1918, i, '84), has now added a sympathetic estimate of his physiological activities at Cambridge during the ten years 1904-14, and writes with a personal touch that is particularly attractive; no one, he says, "who worked with him could think of Keith Lucas except as a friend." His work was entirely devoted to the properties of nerve and muscle. The late Professor H. H. Turner, who was a lifelong friend, and who, with three other contributors, has followed Keith Lucas behind the veil, shows that his versatile genius was largely that of an engineer. This, as is brought out by the three contributors writing on his work in the war, was of invaluable service to the efficiency of the Royal Flying Corps.

The *Proceedings* of the third conference of the International Association of Preventive Paediatrics have now been issued, and the volume contains an account of the two discussions held at Luxembourg in September, 1933. The first of these dealt with the prophylaxis of infantile paralysis and the second with the prevention of what is termed "influenzal diseases in early childhood," although what is meant is the wider subject of catarrhal infections of the respiratory tract. This produced a particularly valuable discussion, emphasizing the danger to the young baby of even simple nasopharyngeal infections among the nursing staff.

Preparations and Appliances

PYELO-LITHOTOMY FORCEPS

Mr. W. K. IRWIN, F.R.C.S. (London, W.), writes: Owing to a slight oversight the first pattern of the pyelo-lithotomy

forceps made to my design was illustrated in the *British Medical Journal* of June 9th (p. 1034). The new model is now shown in the accompanying illustration. It is obtainable from Messrs. Down Bros., St. Thomas's Street, S.E.1.

CONFERENCE OF VOLUNTARY HOSPITALS

A Conference of Voluntary Hospitals in Great Britain and Ireland was held in London from June 13th to 16th under the auspices of the British Hospitals Association and the Incorporated Association of Hospital Officers. It was attended by some 500 delegates of both bodies, and at meetings held at the Guildhall and in the halls of the City Companies a number of papers were read on matters of hospital administration and policy. In the afternoons various London hospitals were visited.

The conference was opened on the first morning by H.R.H. THE PRINCE OF WALES, who was received by the Lord Mayor and the Hon. Sir Arthur Stanley, who acted as chairman of the conference. The Prince expressed his pleasure at meeting such a large gathering of friends of hospitals, and briefly commented upon the various subjects on the programme. He said that one matter in which he himself had been specially interested was the problem of the out-patient department, apropos of the valuable report recently issued by King Edward's Hospital Fund for London. Another matter of great importance to the health services of the country and to the future of the voluntary hospitals was the co-operation between the voluntary and municipal hospitals. The growth in size and complexity of the buildings necessary to provide accommodation for the sick and departmental facilities for their treatment had made the task of hospital building one of very great difficulty, and the conference would have the benefit of a special discussion on the hospital and its architect. The small hospitals had not been forgotten in arranging the programme. Throughout the length and breadth of the land there were some 400 hospitals of small size, all doing good and unceasing work. These hospitals, placed as they were on the main lines of traffic, had had to face a heavy responsibility in connexion with the treatment of the accident cases which were brought to their doors, and he was glad to know that Parliament was now endeavouring to devise legislation which was designed to relieve them of their burden so far as finance was concerned. His Royal Highness also commented on the fact that hospital administration on the Continent was to be the subject of another discussion, for, he said, the hospital world was without national boundaries, and in Great Britain they did not believe that they had nothing to learn from other countries and other systems.

THE OUT-PATIENT DEPARTMENT

LORD MACMILLAN took the chair at the first discussion, which was on the out-patient department, a subject which, he said, to those engaged in the practical work of hospitals, presented one of the most important and difficult problems of administration. The problem had two aspects, one of policy and the other of method. The questions of policy were of this order: whether the out-patient department as now run in most hospitals was best performing the functions which it was designed to serve, from the point of view of attendance by the right type of patient, both in respect to economic status and to the ailments from which those who attended were suffering. The handling of patients in the out-patient department was itself a very difficult problem. It was impossible to deal with it on a merely mechanical and arithmetical basis. The uncertainties of the cases which had to be dealt with must interpose, and the out-patient must resign himself to some period of waiting. He referred appreciatively to the work of the Out-Patient Arrangements Committee, presided over by Sir John Rose Bradford, which was continuing the work of the committee of inquiry set up by the King Edward's Hospital Fund. One of its labours had been to devise standard forms for doctors in sending patients to out-patient departments, and another had been to draw up model time-tables for use in the departments.

THE EARL OF ONSLOW, who acted as chairman of the Out-Patient Committee, said that one of the chief causes of the crowded attendances was the popularity of the

hospitals and their out-patient departments. These departments had the fullest confidence of the public, and it seemed that there were a great number of people who might just as well go elsewhere for their treatment but preferred to go to the hospital. While undoubtedly a certain amount of waiting was unavoidable, much could be done by time-saving methods and also by reducing the number of patients. Old-fashioned and inadequate accommodation was responsible for a good deal of difficulty. It had been asked whether hospitals could not adopt the appointment system, but he thought there would be trouble in carrying that out, partly because of the unpunctuality of patients and partly because such a system would hinder the proper allocation of patients as between consultants and assistants. Hospitals might arrange to provide consultants with secretarial assistance, which would go some way towards alleviating the problem. As for lessening the number of patients treated in hospital, he noticed that the British Medical Association advocated that, except in cases of emergency, no person should be accepted for treatment at a hospital unless he brought with him a doctor's letter. If this was carried out rigidly and logically it would make the out-patient department of all hospitals a purely consultative institution. As a counsel of perfection there was much to be said for it, but he thought it was impossible to make the out-patient department purely consultative. The necessity of obtaining a doctor's letter would be very unpopular. A patient might have the feeling that his doctor did not understand his case, and that he would like a second opinion from the hospital, but he would be deterred if it meant that he had to go to his doctor for a letter before obtaining such second opinion.

AVAILABILITY OF HOSPITAL SERVICES

SIR ROBERT BOLAN, in initiating a brief discussion, laid down four propositions which it seemed to him emerged from the report of the King Edward's Hospital Fund Committee. These were: (1) that the out-patient departments, generally speaking, were so overcrowded that the consultants and specialists working therein were not utilized to the best advantage; (2) the net result of this overcrowding was delay and waiting on the part of patients; (3) the co-ordination between the general medical practitioner services to the community outside the hospital and the consultant and specialist service within the hospital was not yet sufficiently developed; and (4) the only remedy was to educate the hospital-going public by co-operative and sustained effort on the part of the hospitals and the medical profession. The team work in a large hospital, which was so invaluable, inevitably meant delay, but it had also to be remembered that the consultations with the other consultants and specialists and the particular services available at a well-equipped hospital could furnish the required service to the patient in as many hours as it needed days in the case of the private citizen seeking medical aid in the usual way. Some economy of time might be made, and a great deal of exasperation saved, if a fuller use were made of informative and directional signs for the benefit of those who were not regular habitués of the hospitals. Was it too much to hope that in the ideal hospital of the future the anxious patient would encounter an experienced and courteous usher, with sufficient subordinate messengers to deal with those who could not find their way without personal assistance? The matter of dispensing had aroused some criticism and attention. The prescription habit in the British nation had become very much more common since the period of national health insurance, and some large hospitals used the prescription system extensively instead of maintaining large dispensaries. The day had gone by for such slogans as "The ever-open door," "Free service to all," "No one turned away," because these gave rise to the mistaken impression that the hospital was available for all kinds of services, and that was an uneconomic proposition. The time had come to teach the hospital-going people what services were available in the hospital, and how such services differed from the kind of services obtained at the hands of the

general practitioner outside. With regard to doctors' letters, Sir Robert Bolam affirmed that the proportion of doctors who resented having to refer their patients to a hospital or consultant was negligible. In ordinary life the general medical practitioner was the sifter of cases. A good many matters he could deal with personally himself. Others had to be referred to consultants and specialists for admission to nursing homes or hospitals. It would seem that to use a consultant or specialist as the sifting agent in a general hospital was to put him to do general practitioner work. One would be far from denying that there were a good many who would do this very well, but was it in fact what the consultant was appointed for? Most hospitals relegated the sifting process to a junior member of the staff, and that junior member was acting in such a capacity as a general medical practitioner. It followed that as much of this discriminating process as possible should be done before the patient reached the hospital, and therein lay the value of the doctor's letter. The residuum of persons who had difficulty in finding a doctor to recommend them to a hospital nowadays must be very small. It was only where the public medical assistance was not fully developed that such could be the case. It was not beyond the bounds of possibility that a public authority should make an arrangement with the hospital to provide a public assistance medical officer to take part in dealing with such cases. In conclusion, the hospital habits of our people would not be changed in a few days because decisions were made and principles enunciated, and whatever the plight of the institutions or the wish of the profession might be in this matter we would be well advised to recognize the essential conservatism of the rest, and be satisfied with reasonable progress towards the consultative ideal to be attained within the next four or five years.

THE PRIVATE PRACTITIONER

In further discussion, Sir HENRY BRACKENBURY replied to Lord Onslow's comments on the British Medical Association proposition that the out-patient department should be confined, or almost confined, to consultative work. There were actually hospitals which had converted their out-patient departments practically into consultative departments, so that the proposition was not as impracticable as might be supposed. But the fundamental idea was that the hiatus between the field of hospital work and the field of private practitioner work should be eliminated. One of the present evils was that the hospital field of work and the private practitioner field had been to a large extent divorced from one another. In some ways that had been the fault of the teaching hospitals in the past, but he was sure that the young student just qualified and the resident medical officer in the hospital had got into their heads somehow or other that the general practitioner outside was somebody who was not very well worth considering, and need not be considered very much in relation to the amount of work which they had been accustomed to observe from the hospital staff point of view. That was a wrong notion; the general practitioner outside in his ordinary surroundings was much more capable of dealing with and helping the patients who came to the out-patient departments than anyone else. Therefore it was of the utmost importance that the general practitioner outside, doing the domiciliary work, should be considered an essential part of, and in very close association with, the work of the hospital itself. From that point of view there was much to be said for insisting that before the patient went to hospital the opinion of the general practitioner should be considered. Not only so, but when hospital attention was no longer necessary for the patient, although he was still not perfectly recovered, it was most desirable that he should be referred to the general practitioner for care instead of being continued in the out-patient department of the hospital. It should be primarily the family doctor to whom such patients were referred, and not primarily the district nurse.

Time did not allow any further discussion, but the applause which greeted Sir Henry Brackenbury's remarks suggested that this point of view was not unacceptable to hospital administrators.

CO-OPERATION BETWEEN VOLUNTARY AND MUNICIPAL HOSPITAL AUTHORITIES

At a later session, under the chairmanship of Lord RIDDELL, the subject of co-operation between voluntary and municipal hospital authorities was discussed.

Sir GEORGE NEWMAN, in an opening paper, gave a table representing the present hospital accommodation in England and Wales. This showed that the number of hospitals provided by local authorities was 858, with 143,494 beds, and the voluntary hospitals numbered 988, with 71,956 beds. Of the local authorities' hospitals, 326, with 57,129 beds, were provided under the aegis of the public health, and 532, with 86,365 beds, under the aegis of public assistance. Of the hospitals not provided by local authorities, 663, with 49,673 beds, were general, and 325, with 22,283 beds, were special.

It was clear, said Sir George Newman, that the only sensible course to pursue was to develop a practical and unified system of co-operation between these two classes of hospitals. As a result of the Act of 1929, many of the former Poor Law hospitals had become municipal hospitals for the benefit of the public in need of medical treatment, and not, as formerly, for the destitute poor only. Thus there had been created the beginnings of a national hospital system. As the municipal hospitals expanded there might seem to the casual observer to be less need of the voluntary hospitals. Which was the wiser: to put all hospitals, voluntary and municipal, on a municipal basis of rates and taxes, and allow the voluntary movement to disappear, or to combine the two in one co-operative hospital system? He was strongly in favour of the latter course, and believed that a co-operative system was likely, if properly organized, to be more economical in the long run than a rate-aided State system without the voluntary element, and it provided for the peculiar English genius a practical compromise between collectivism and individualism. He asked the gathering to consider what the voluntary hospital had done. It had encouraged the pioneering spirit of discovery which had strangely but steadily led English medicine hitherto. For more than 200 years it had provided ways and means for the foundation and development of all the great schools of medicine in the universities, and in its atmosphere had been trained, among others, all the doctors for all the municipal hospitals. A teaching hospital, like a university, lived by unhampered freedom of thought, and in their national hospital system the English people would do wisely to provide ample room for the exercise and application of the voluntary system. But the ever-widening and important medical needs of the population had not been met in the past, and could not be met in the future, wholly by voluntary hospitals. The municipal hospital represented the formulated will of a free people. It was a hospital provided by the State, deriving its sustenance from rates and taxes, its direction from the elected representatives of the municipality, and its authority from Parliament. It was between these two types of national institutions that the Act of 1929, followed by the Minister's circular, had sought to ensure co-operation. The authorities and the voluntary hospitals had not put into the fullest operation of which they were capable the powers afforded by that Act. But more had been done by the State in support of voluntary hospitals than some persons appeared to assume. Financial grants had been furnished by local authorities for new buildings and equipment. Special grants had been made for the treatment of various conditions. Only a few days ago a county council made a grant of £10,000 towards the rebuilding of a voluntary hospital. The London County Council was paying grants at a yearly rate of £250,000 to voluntary hospitals, and upwards of £125,000 was paid last year by approved societies for the in-patient treatment of insured persons in those institutions. Further, there had been much interchange of function, of the services of consultant staff, and of the use of special beds, apparatus, or installations as between the two types of hospitals. It could not be said that even yet in all areas there was real and effective consultation or co-operation. Such consultation was a statutory obligation, but it could not take place until

the voluntary hospitals of the area and their medical staffs had established a representative committee, had informed the local authority of its existence, and were prepared, jointly with the authority, to consider the institutional and hospital requirements of the district.

NO WASTEFUL COMPETITION

In conclusion, Sir George Newman permitted himself four general observations. The greater the good will and genuine desire for co-operation for the common good, the more fruitful would be mutual consultation. The survey reports of the medical officers of the Ministry showed that the desire for co-operation was widespread, and that many forms of practical co-ordination were being practised on both sides. But there was some fear on the part of voluntary hospital representatives that local authorities intended to compete unduly with the voluntary hospitals. As a fact, however, public authorities could not afford to engage in wasteful competition or the duplication of existing facilities. The local authority, while it should not attempt to compete, had a definite statutory responsibility to the community to supplement the work of voluntary hospitals and fill gaps which the latter were unable to fill, or had not in fact filled. It was obligatory upon the authority to consult with representatives of the voluntary hospitals when providing, allocating, or adapting its accommodation in discharge of the functions with which it was entrusted, and it was obvious that such consultation should take place before the decisions of the authority had been reached, and not only afterwards. Finally, the local authority should do all that was practicable, with foresight and prudence, to foster and aid appropriate voluntary organizations in its area, both for hospital services and for the development of public health provision of the people, which were implicit in the new organization laid down by the Act. On their part also the voluntary hospitals in every area should create competent and representative bodies to organize and co-ordinate their own work and to consult with the local authority on hospital needs.

Lord COZENS-HARDY said it was taking the voluntary hospitals a very long time to realize the enormous changes in the hospital system of the country which must ensue from the Act of 1929. The voluntary hospitals had been inclined to be suspicious of that Act and of the wide powers and duties which it conferred upon local authorities. The Act itself limited compulsory consultation to a narrow field, and the extent of co-operation would depend upon the attitude of the Ministry and the direction in which the Ministry encouraged the local authorities to move. The early circulars of the Minister seemed to point in the right direction, but not perhaps so clearly as to remove suspicion from the minds of the voluntary hospitals. A clear pronouncement, such as had been given by Sir George Newman, that there were important functions, such as teaching and research, which the voluntary hospitals could best perform in the interests of the community, was to be welcomed, also that the hospital service as a whole could not produce its best results without close and continuous co-operation between the local authorities and the voluntary hospitals. What was needed was something more than a mere "Section 13 body" but a joint committee between the local authority and the voluntary hospitals meeting regularly to consider everything bearing on the hospital service as a whole. Proposals for extensions, whether by the local authority or by the voluntary hospitals, should be considered by some such committee before action was taken.

CO-OPERATION OF HOSPITALS IN MENTAL HYGIENE

Mr. L. G. BROCK (Chairman of the Board of Control) gave some practical illustrations of co-operation between voluntary hospitals and municipal institutions in the field of mental hygiene. For some years there had been a growing co-operation between the London mental hospitals and the London medical schools. The mental hospitals realized that many of their patients were physically very sick people, so that an arrangement had grown up whereby there was an informal alliance between the mental hospital

and the medical school, the latter providing the consultants who came regularly to visit new patients in the mental hospitals, while the mental hospitals provided the psychiatrists for the instruction of the medical students. A second form of co-operation was in the provision of out-patient mental clinics by voluntary hospitals, following the passing of the Mental Treatment Act.

Dr. C. E. S. FLEMING said that it was for the voluntary hospitals to adopt and adapt such of the methods of the municipal hospitals as they could usefully employ, including co-ordination and co-operation, and economy in buildings and maintenance. They prided themselves upon their "voluntaryism," but it must be remembered that a volunteer was of no use unless he was a member of an organized army. Voluntary hospitals must cast aside that parochialism which had been their weakness in the past, otherwise they would not be able to hold their position in the hospital service of the country. Already the municipal hospitals were in close competition with them on one point—namely, in the open market for medical officers—and as to whether the prestige of the voluntary hospitals would enable them for long to obtain the men and women they wanted he was rather doubtful.

A number of lay hospital administrators from various parts of the country contributed briefly to the discussion. A Gloucestershire representative urged the importance of endeavouring to get the chairman of the voluntary hospital elected a member of the local authority. Following on this point a Moxborough representative said that four members on his board of management were members of the West Riding County Council, and one of them was chairman of the Public Health Committee. A Sheffield representative said that his was one of the first cities to create a co-ordinating committee between the municipality and the voluntary hospitals. There were four voluntary hospitals in Sheffield, and they were all represented on a committee which included also representatives of the municipality, and the chair was filled in alternate years by a municipal and by a voluntary hospital representative. An arrangement was also in being whereby a considerable number of patients coming to voluntary hospitals were transferred to municipal hospital beds.

Lord RIDDELL, in closing the discussion, referred to the excellent results which had already been achieved by the Joint Hospitals Committee in London.

THE COTTAGE HOSPITAL

Other discussions at the four days' conference must have briefer mention. Mr. W. M. GOODENOUGH, honorary treasurer of the Radcliffe Infirmary, Oxford, read a paper on the function of the cottage hospital. Its main function, he said, was to deal with minor medical and surgical cases which did not call for special treatment, but it might have a further use for convalescent cases, and perhaps as a residential centre for district nurses. Lord HORDER, who took the chair at this discussion, referred to the various therapeutic assets of a cottage hospital—its quietness, its proximity to patients' friends, and its adaptability to the work of routine observation. Dr. C. E. S. FLEMING preferred the term "district hospital," which suggested that it was for the people of the district and staffed by district practitioners. Specialist members of the staff of the central hospital should be available, but only for the purpose of consultation or emergency operation. There was a tendency in some of these hospitals to expect the work to be done by members of the staff of the central hospital. One objection was the possibility of complications arising after operation, when the specialist himself was not present; another was that the extra equipment and nursing for this kind of work imposed an unusual strain on the small hospital. On the other hand, minor cases—a term the speaker disliked—were pre-eminently suitable for the care of the practitioner at the district or cottage hospital. These small institutions were distinctly needed for the completion of the hospital service of the country, and it might be very dangerous to interfere with their development by rigid rules.

HOSPITAL ADMINISTRATION ON THE CONTINENT

Dr. RENÉ SAND, technical counsellor of the League of Red Cross Societies, gave an address on the situation of hospitals on the Continent. His account of the municipal hospitals of France was a little depressing. Too economical administration, overcrowded wards, non-recognition of hospital technique, superannuated buildings, lay superintendents—"nobody is satisfied, but the system is such that nobody could be." Improvements were, however, taking place. In Paris the maternity hospitals and many surgical departments now ranked as excellent. Lyons was building well-equipped hospitals. The new hospital in Rheims kept half its patients in single rooms, and no ward had more than four beds. Nancy and Strasbourg had models of hospital administration and building. Lille was planning a huge hospital centre of 5,000 beds in two buildings of thirty floors each, walled entirely by steel and glass, and ventilated by conditioned air. New resources were being opened up by sickness insurance funds, which paid for the hospital treatment of ten million members, and the insured population was insisting on better hospital conditions.

In a brief survey of other countries, Dr. Sand said that Italy was rapidly renovating its hospitals; eight great hospitals had been opened in recent years, eighteen were being built, and many more were planned. Rome, Milan, Turin, Venice, and Naples would soon have a complete and modern hospital system. Spain was making great strides, and there were few out-patient clinics in the world to rival the Red Cross dispensary in Madrid. In Austria there was a hospital plan for the whole country, which was divided into hospital districts. In Scandinavian countries the planning, maintenance, and administration of hospitals had been for centuries the function of the State, the countries, and the great cities. In these countries, as well as in Germany, Holland, and Switzerland, the hospital superintendents were generally doctors. He had visited only a few hospitals and maternity institutions in Soviet Russia, and he spoke of them highly. In Germany the economic crisis had compelled some hospitals to close wings and curtail staff, but difficulties there as elsewhere had the advantage of fostering initiative and devotion.

HOSPITAL ARCHITECTURE

Mr. STANLEY HALL read a useful paper on hospital architecture. The choice of a building committee, he declared, was almost as important as the choice of an architect. The most satisfactory way of co-ordinating the various interests was to appoint a technical committee of physicians and surgeons, who would report to a very small lay committee directly responsible to the board. The work of the technical committee should be to obtain from all the specialists their requirements as to particular departments, to decide upon the order of urgency, and to determine, and if necessary to limit, the requirements of each specialist. The total number of beds required must first be settled; then the question of the number of patients for each nursing unit, which was a very important instruction for the architect before planning his ward blocks. The number and disposition of the operating theatres had next to be settled. A grouping of theatres into one unit was advantageous economically; twin theatres could often share one large sterilizing room and plant. The accommodation of students in theatres in teaching hospitals was a tax on the resources of the architect. Casualty and out-patient departments were various in their methods of working. The number of medical and surgical consulting rooms must be settled according to the number of honorary officers and assistants who would be holding sessions at the same time. Mr. Hall dealt with other points of detail, such as the housing of the nursing, domestic, and administrative staff, the boiler-house and other services, and the pathological block. Having cut out the parts of the jigsaw puzzle, the next business was to place them in their correct relation. The casualty and out-patient departments must be easily accessible to the public.

THE ALMONER'S WORK

The final discussion was on aspects of almoner's work. Miss CHERRY MORRIS, lady almoner of St. Thomas's, said that the ideal of the almoner was to secure the maximum of necessary information with a minimum of inquiry. She must be just alike towards the patient and towards the hospital, must not make demands on patients which would entail too great a sacrifice, and must not let herself be deceived by plausible persons. The future of almoners' work was threatened by a real danger, just because the almoner had shown herself too good a financier. In the minds of certain people—and some of the medical profession were not blameless—the financial side had been stressed to the exclusion of everything else. The question before hospital boards was often not whether the almoner would increase the efficiency of the hospital, but whether her department could be made to pay. If this tendency grew the consequences would be serious. Medical men would lose what was potentially a valuable auxiliary service in the treatment of the sick, for the almoner's profession would cease to attract to its ranks the best type of educated woman.

GUILDHALL BANQUET

A Guildhall banquet, over which H.R.H. The DUKE OF YORK presided, and which was attended by about 600 guests, was held in connexion with the conference. The Lord Mayor and Lady Mayoress were present, and in every part of the hall one saw people prominent in hospital administration and service. The Duke of York spoke of the great work of the voluntary hospitals in tending the sick and suffering, educating medical students, and investigating the causes of disease. On many occasions since the war, he said, members of his family had been associated with appeals for funds, and had been in a position to appreciate at first hand the results of this work. He felt that in difficult times the way in which the public had contributed to hospitals had been quite wonderful.

LORD STANMORE, treasurer of St. Bartholomew's, said that although the financial difficulties of the voluntary hospitals were very much to the fore, even during the blackest financial period of this century the hospitals as a body had ended each year with a substantial credit balance, and in the history of any individual hospital over a period of years the balances of the credit years weighed down the scale against the balances of the years of deficits. The threat of closing down was often heard, but instances of any institution closing down for lack of funds were almost unknown. He spoke also of the elasticity of the voluntary system. While it clung to certain traditions, it had been able to adjust itself to conditions which in any progressive country were constantly changing. It could not, of course, meet all needs. There were those for which only the State could provide, and the voluntary hospitals were anxious to co-operate in every possible way with the State; but within their own boundaries they could and did provide that which from time to time was found to be necessary. He referred especially to the provision of hospital beds for those who had in the past been accustomed to be treated in times of sickness in their own homes.

LORD HORDER, in responding to the toast of "The Guests," said that many of those present were rather incongruously described as guests. Sir Holburt Waring, President of the Royal College of Surgeons, for example, had been intimately associated with hospitals throughout his career, and Sir Henry Brackenbury, Chairman of Council of the British Medical Association, had with others on that body done much to formulate a hospital policy in which the general practitioner had his place. The British ideal of the voluntary system was a noble one, but it needed watching, and its friends were not altogether happy in all respects, especially with regard to the undignified manner in which financial support was sometimes sought. Although he personally felt that the voluntary system, breathing as it did the spirit of freedom and independence, would and must go on, this did not mean that some methods employed on its behalf were of permanent value, or that it would not have to adapt and change itself to changing conditions.

British Medical Journal

SATURDAY, JUNE 23rd, 1934

THE WAR AGAINST CANCER

Dr. Jacques Bandaline's monograph on the international war against cancer,¹ to which the Joest Prize for 1933 has been awarded by the Académie des Sciences Morales et Politiques, was originally written to appear in connexion with the International Cancer Congress held at Madrid in October, 1933. Its preparation has occupied the author's whole time since 1926, and it provides an exceedingly interesting and complete summary of cancer research up to the date of its appearance. Only those who have themselves been employed on literary research work can appreciate the magnitude of the task undertaken by Dr. Bandaline, the almost infinitely scrupulous attention to detail and the linguistic attainments which have made its publication possible. The author is to be warmly congratulated upon the successful achievement of a truly herculean task. Work of this kind is, we think, but seldom appreciated at its true value, and too often there is a tendency to undervalue the inestimable importance of scientific literary research work. Laboratory and clinical investigations are of necessity scattered among a vast number of publications, which, needless to say, are written in as many languages as there are nationalities represented. Any comprehensive review of such work requires, in addition to an adequate knowledge of several foreign languages, a critical examination of the scientific value of the papers laid under contribution, and thus a combination of attainments of no common order.

In Dr. Bandaline's work the reader will find a historical summary of the cancer question, commencing with a brief account of mention of the disease in the Rig-Veda and the Ebers papyrus, through the Greek period and the Latin and mediaeval schools up to the present time. Obviously we have not space at our disposal for even a cursory glance at these matters, which in themselves are of absorbing interest. Passing to the eighteenth century we read how, probably owing in part to error of diagnosis, the disease was regarded as contagious, a view which led to the infliction of unnecessary cruelties upon the unfortunate sufferers from a terrible disease. They were excluded from the general hospitals—in France at any rate—and forced to shift for themselves as best they could. It was to a canon of Rheims, Jean Godinot, that we owe the foundation of the earliest cancer hospital, which was opened in that city in 1740, and was equipped with the modest number of twelve beds. Even then the dread of the infectious nature of the fell disease alarmed the citizens, and in 1779 the hospital was moved to La Buërie in connexion with additions to the Hôpital St. Louis.

At that time, of course, nothing was known of the nature of infection or of the methods by which it could be dealt with, so that the citizens of Rheims must not be judged too harshly for the infliction of cruelty which had its origin in panic and ignorance. To France, therefore, must be accorded the honour of having provided the first hospital for the treatment of patients suffering from cancer, to the special investigation of which Dr. Bernard Peyrille of Lyons devoted his attention. In England the place of honour must be accorded to the Middlesex Hospital, with the formation in 1791 of its Cancer Charity, which has devoted unremitting attention to the subject up to the present time.

From time to time theories of the causation of cancer were propounded and methods of treatment suggested, but it was not until 1901, when the work of the Danish pathologist Jensen appeared, that the modern era of scientific and systematic research commenced. In this country the Imperial Cancer Research Laboratories were opened in 1902, and at intervals institutions upon similar lines have been formed in most civilized countries. Dr. Bandaline has obtained official information upon the work of these bodies in no fewer than sixty-one different States, so that his book gives a view at once comprehensive and authoritative of cancer research work all over the world. In many, at any rate, of these countries the question of educating the public upon the subject of cancer has been assiduously pursued, and in the present state of our knowledge this is undoubtedly the sphere in which the general practitioner can contribute assistance of inestimable value in the world-wide campaign against cancer. By emphasizing the fact that cancer, *if taken in time*, is frequently amenable to treatment by modern methods, and that radiotherapy in many cases has supplanted those mutilating and devastating operations which were formerly regarded as necessary, he can reassure those who are in doubt but are afraid to face the truth. The remarkable results which have followed the use of radium and x rays in the treatment of, for example, cancer of the cervix uteri and of the tongue should be sufficient to demonstrate what has been achieved in this direction.

One of the great difficulties attending the treatment of cancer with any hope or possibility of success has been the delay, usually prompted by fear, in seeking medical advice. Not unnaturally both the patient and the family medical adviser felt that to get a definite diagnosis of cancer was equivalent to passing sentence of death. Delay means simply that a condition which in its early stage will respond to treatment has become so extensive or so disseminated that when submitted for expert advice it has become almost hopeless. In cases judged inoperable or incurable much can still be done by radiotherapeutic methods to render the patient's remaining span of life much more tolerable and often relatively comfortable. It has been shown how in the past a false conception of the infectious nature of cancer must have inflicted almost incalculable suffering; it is for us to see at the present time that

¹ *La Lutte Internationale Contre le Cancer*. Par Dr. Jacques Bandaline. Paris: N. Maloine. (135 fr.; abroad, 145 fr.)

equally unnecessary suffering is not caused by delay. Above all, even if the disease is not seen until it has become inoperable and apparently "hopeless," yet relief is generally possible, and that to an extent which must be seen to be believed.

HYPERINSULINISM AND DYSINSULINISM

The conception of hyperinsulinism and its establishment as a clinical entity was first considered by Sealé Harris in 1923, soon after the general appreciation of the importance of the discovery of insulin itself. Since then many cases of hyperinsulinism have been described, which have varied from a transient postprandial hypoglycaemia to most severe hypoglycaemia with shock, convulsions, and coma. In a recently compiled series of 1,497 non-diabetic cases Harris found that the fasting blood sugar in fifty-one patients was abnormally high, and in sixty-seven abnormally low, from which he concludes that "hyperinsulinism occurs almost as frequently as hypo-insulinism." He recommends the estimation of blood sugar and glucose-tolerance tests in cases of unexplained nervous attacks, periods of unconsciousness and convulsions, and in cases where the diagnosis of grand mal or petit mal may seem a little doubtful. It is within the experience of everybody that many people complain of a "sinking feeling" between meals, and that such persons soon learn that the ingestion of chocolate or food of carbohydrate nature rapidly relieves them. Physiological hyperinsulinism is readily seen in many cases after the test dose of glucose in a sugar-tolerance test, the blood sugar at the end of two hours or so often falling much below the initial value. This used to be explained as a stimulus to the glycogenic function of the liver, but there seems now little doubt that it is due to a stimulus to the insulinogenic processes.¹ Harris suggests that such physiological hyperinsulinism, when excessive, may, by exhaustion of the islets, lead to diabetes, and by the stimulus of excessive hunger (a symptom of hypoglycaemia) lead to the exogenous obesity which so often precedes diabetes. Such cases are readily treated by restriction of the insulinogenic stimulus—namely, carbohydrate—and more frequent feeding. Very severe cases may need glucose. Such excessive hypoglycaemic responses may arise from factors other than the secretory activity of the islets of Langerhans—for example, inadequate function of the adrenals and the pituitary.

Most striking are those cases of hyperinsulinism which are attributable to an adenoma of the islet tissue. An addition to the reports of such cases has recently been made by Ross and Tomasch.¹ Their case was a man of 33 who had been brought to hospital as a "drunk," having fallen in the street and sustained considerable injuries about the head. After a series of investigations it was found that he was a case of hyperinsulinism, and that on a diet of 1,800

calories with 60 grams of carbohydrate he developed hypoglycaemia shocks (blood sugar 23 mg. per 100 c.cm.) every six hours or so. A striking feature in these patients is that glucose-tolerance tests give curves starting at hypoglycaemic levels but rising to very high values, and maintaining a diabetic character for some time, without, in some instances, giving rise to glycosuria. Laparotomy revealed a cystic nodule in the pancreas, the removal of which led to complete disappearance of the syndrome. Histological examination showed that the nodule was a tumour of the islet tissue. These authors confirm the finding of others that in hypoglycaemic coma the plantar response is extensor—of diagnostic importance particularly where diabetic coma might be suspected, the response in the latter being flexor. Recently a very thorough study of five adenomata of the islets has been made by O'Leary and Womack.¹ The best methods were used by these workers for demonstrating the characteristic granules of the islet cells, and careful comparisons with normal cells were made. The tumours were in general small, but in one instance the dimensions were 9 cm. × 9 cm. × 11 cm., the tumour being nodular and cystic. Certain definite differences were recorded between the histological properties of the granules in the tumour cells and those of normal islet cells, indicating that the syndrome of hyperinsulinism may be due to a modified form of insulin and not merely to an excessive secretion of the normal hormone. These findings were all the more interesting in that the pancreatic islets adjacent to the tumour islet tissue were quite normal in their histological characteristics. Autolytic changes produce marked changes in normal islet cells in a short time, but tumour islet cells are for some reason remarkably resistant to this process and retain unchanged their histological characters even after twenty-four hours in Ringer solution. The evidence goes to show that in the tumour the cells are all of the β -cell type, with greater or less modified staining affinities. The tumours all contained small ducts histologically akin to the smaller pancreatic ducts, and evidence was obtained of the differentiation of duct epithelium into islet tissue, which shows that the duct cells are capable of giving rise to both the externally secreting acinar tissue and the internally secreting islets.

TUBERCULOSIS IN CHILDREN

The correspondence which followed our last reference to this subject² was one indication of the increasing interest shown. It is perhaps disappointing that investigation in England of many of the difficult aspects of tuberculosis in childhood seems to lag behind that in other countries, notably Scotland, France, Germany; and the United States. Recently in these columns Dr. G. G. Kayne described³ how Professor P. F. Armand-Delille and his pupils in Paris are correlating the clinical and radiographic findings during life with the

³ *Ibid.*, March 3rd, 1934, p. 370.

¹ *Arch. of Surg.*, February, 1934.

pathological state discovered at necropsy. Somewhat similar work is described in a paper¹ from the departments of paediatrics and pathology of Yale University School of Medicine, one of a series of papers dealing with work made possible by a special research fund and carried out for the research committee of the National Tuberculosis Association. Dr. Margaret L. Bronson and her colleagues have studied the radiographic appearances of the chests of fourteen children, and have correlated these with detailed clinical and pathological data. The records in certain instances cover a period of years, with a whole series of x-ray examinations. A large group of radiograms from children with non-tuberculous conditions of the lungs was also taken into consideration. Since the study was essentially based upon the x-ray findings the details of the methods used are important. It is recommended that radiograms should be taken with the chest in the position of complete inspiration; six-foot target-film distance is held to be best; oblique views of the thorax to demonstrate the mediastinum are mentioned as important; and the necessity of enough exposure to bring out calcium deposits is emphasized. Various points of great importance emerge from these studies. For example, large homogeneous lobar shadows, mottled shadows (localized or disseminated), and even "so-called" "infiltration" may or may not be due to tuberculosis. The close resemblance between the radiographic appearances of non-tuberculous and tuberculous conditions means that the demonstration of cavity formation or of the presence of calcium becomes very valuable in favouring the latter. Another point well illustrated in the present series is that a radiogram is sometimes essentially negative, although the thoracic contents of which the film is a projection are extensively involved in proved pathological processes. A second paper² in this series deals with pulmonary tuberculosis in infants under 2 years of age. Dr. Ethel Dunham shows convincingly the paramount importance of direct exposure to infection from human sources. In the seven cases studied in detail in her series the mother was the source of infection in three, and in one case each the father, a sister, a nursemaid, and a cousin living with the family. Four of these persons were known to have positive sputa, and the other three died of tuberculosis subsequent to the exposure of the infants. A second point of interest emerging from this study is that, while the ultimate fate of such young subjects must remain doubtful until far more extensive follow-up investigations have been carried out, it is certainly becoming more and more realized that previous work, based so much upon hospital statistics, has exaggerated the mortality at this young age. Four of the seven children in this series are considered well some years after first coming under observation, two are still under treatment, and one died of tuberculous meningitis at the age of 5 years. A third study³ may also be briefly mentioned here. It concerns the somewhat vexed question of the relation of phlyctenular conjunctivitis to tuberculosis. Drs. M. Goldstein and C. L. Wood have studied seventy-one children from 10 months to 12 years of age with this condition of the eyes, and they adduce very strong evidence of

underlying tuberculous infection in the majority of cases. Tuberculin tests, x-ray examinations not only of the chest but also of the neck, abdomen, and the bones, in a search for a possible tuberculous focus, positive history of contact, and physical signs of tuberculosis, all came into consideration; the combined evidence makes an impressive and convincing case. The importance of radiological examination of the neck is a novel point, and it is interesting that the only x-ray evidence of tuberculosis was found in the neck and abdomen in eighteen instances—nearly 40 per cent. of the positive films.

ASPIRATION TREATMENT OF LARYNGEAL DIPHTHERIA

The investigation of cases of laryngeal diphtheria by means of direct laryngoscopy and their treatment by mechanical suction of recent years has made slow if definite progress. In this country the work of Joe¹ and Benson² has familiarized us with the procedure, and though a steadily diminishing incidence of croup appears to be one of the main features of the present epidemic type of diphtheria, and consequently not the problem it was a decade ago, it is gradually being taken up by the large infectious hospitals: the published results in Great Britain indicate that a properly cautious attitude has been maintained. It is agreed that valuable aid in diagnosis and treatment may be obtained, but in all series of cases a larger or smaller proportion have ultimately required intubation or tracheotomy. It is interesting, therefore, to compare these views with those of Lemariey and Hamon,³ who give an account of four years' experience of the procedure in Paris. Their technique is the same as generally practised, except that they prefer a suction cannula with a blind end and one or two lateral fenestrae near the tip instead of one with a terminal opening, and in addition to clearing out the larynx and trachea they apply suction to the main bronchi when necessary. Compared with the older operation of indirect intubation they claim advantages in respect of the fact that instruments are directly under visual control; the procedure can be applied to an oedematous and ulcerated larynx; hoarseness and aphonia are less persistent; and they have not encountered a single case of chronic stenosis. Heart failure, which Lemariey and Hamon regard as one of the most noteworthy complications during intubation, is rare in aspiration, and respiratory difficulties during suction can be quickly countered by the introduction into the trachea of a cannula transmitting oxygen. Their assertion that intubation renders the feeding of the child practically impossible is difficult to understand, but the easier feeding of the aspirated patient is also claimed as an advantage. They regard aspiration as the only rational method of treatment of tracheo-bronchial diphtheria, and believe that in cases complicated by bronchopneumonia aspiration of secretions followed by intra-tracheal oxygen is at least of temporary benefit. As a result of their observations Lemariey and Hamon have classified the various forms of croup as follows.

¹ Report to the Metropolitan Asylums Board, December 10th, 1923.

² *Lancet*, October 31st, 1931, p. 856.

³ *Ann. d'Oto-laryngol.*, 1934, ii, 101.

¹ *Amer. Journ. Dis. Child.*, 1934, xlvii, 104.

² *Ibid.*, 1934, xlvii, 149.

³ *Ibid.*, 1934, xlvii, 171.

In benign croup, membrane is present only on the epiglottis and the cords, the subglottic space being free. Results in this form are always favourable, and nine successful cases are reported. Severe croup is distinguished by extensive thick membrane involving the larynx, the subglottic space, and the upper part of the trachea, and four patients came into this category. All recovered—three after aspiration alone, but in one case tracheotomy had to be resorted to. Septic croup is defined as a condition in which mucopurulent membrane covers an oedematous ulcerated mucosa, and an associated bronchopneumonia is the rule. In seven such cases only two recoveries were obtained, all except one, a recovery, being complicated by bronchopneumonia. Tracheo-bronchial diphtheria is disclosed by the presence of membrane in the upper part of the trachea, by the aspiration of bronchial casts, and by the broncho-pulmonary type of dyspnoea: eight cases of this type are reported with four recoveries; three of the cases complicated by bronchopneumonia were fatal. The authors consider that it is in this form that aspiration gives the most striking results, since with intubation or tracheotomy the prognosis is hopeless or very gloomy. Infantile croup is relegated to a category by itself, and is distinguished by the gravity of the dyspnoea, stridor, and profound toxæmia. Three cases of this type succumbed to bronchopneumonia, one to heart failure, whilst one recovered. It is always difficult to prognosticate whether any given case of croup will require operation and will not yield to expectant treatment, but it is a fact that a proportion do. Taking the results of tracheo-bronchial diphtheria alone, however, the results are very encouraging. The authors expressly disclaim any intention of entering into the respective merits of intubation and tracheotomy, but they seem to have had an unfortunate experience of the former. It is curious, therefore, that they have not considered the method of direct intubation by means of the laryngoscope, to which several workers in this country have turned their attention.

TECHNICAL METHODS IN MORBID ANATOMY AND HISTOPATHOLOGY

Outlining a new editorial policy in the March (1934) issue of the *Journal of Technical Methods and Bulletin of the International Association of Medical Museums*, No. XIII, Dr. Robert A. Moore, for the Editorial Committee, points out that a distinct contribution to the systematic indexing of scientific material would be made if the periodical mentioned above were to confine itself exclusively to communications directly concerning these fields. He states that, though there are three large national journals dealing with morbid anatomy and histopathology in the English language, his alone is devoted to technical methods with special reference to museum and laboratory procedures. It is therefore intended to limit the scope of the bulletin of the association to museum and necropsy technique, photographic methods, microscopical technique (especially as applied to museum material), injection methods, and teratology, especially congenital anomalies of the heart. The bulletin is to be made an annual publication, and will still contain the proceedings of the association and reports on its special activities, more particularly those of the International Index of Medical Museums. The

present issue, which runs to 200 pages, includes editorials, descriptions of museums, book reviews, proceedings, and reports. A considerable number of pages are devoted to original communications on such subjects as museum administration, cataloguing, etc., museum and necropsy technique, photographic methods, microscopical technique, and a number of case records. The volume, edited, like its predecessors, by Dr. Maude Abbott, is well illustrated, and should prove of the greatest interest to those concerned with the teaching of morbid anatomy, histology, and pathology in general.

A NUTRITIONAL STUDY OF BELGIAN UNEMPLOYED

An investigation into the living conditions and budgets of insured unemployed in Brussels was carried out in 1932, and the sociological results have already been published. Bigwood and Roost now record the nutritional data under the title *L'Alimentation Rationnelle*.¹ The facts were obtained from a month's study (January to February) of nineteen families, chosen at random from the lists of unemployed, which comprised ninety-three persons. Quantities of foodstuffs bought or given were entered into notebooks. The analyses of foodstuffs used for computation were chiefly those of Van de Weyer for Belgian produce, with special analyses where necessary. Foodstuffs as consumed, probably did not vary more than from -3 to +3 per cent. from analytical tables. Refuse ranged from 7.5 to 14 per cent. of total foodstuffs as bought (average 11 per cent.), high percentages being obtained chiefly where the amount of potatoes was large. Plate-waste was calculated as 1 per cent., intestinal waste as 4 per cent.; protein and carbohydrate were calculated to yield four calories per gram, fat nine calories. Complete tables are given for each family for gross and net calories, grams of animal and vegetable protein, fat, and carbohydrate. The percentage amount of the total gross weight supplied by the various food groups averaged: meat, 9; cereals, etc., 55; vegetables, 6; fruit, 2; fats, 3; eggs, 1; milk, 18; cheese, 0; various, 6. Family coefficients according to different scales are compared, and that adopted takes the woman as unit and allows her 2,600 calories net, the unemployed man being allowed 2,400, or 0.90, and children scaled down according to age to 0.25 for a child under 1 year. The authors reckon that the League of Nations scale of calorie requirement is slightly below that of the Belgian people, as shown by Slosse's investigation into 1,065 working men in 1910. The net calories of the nineteen families varied from -33 to +30 per cent. on the Bigwood-Roost scale, five families being more than 10 per cent. below and therefore certainly receiving insufficient food. Protein averaged 81.5 grams per unit, with a range of 55 grams to 105 grams, of which the animal protein averaged 40 per cent. (range 27 to 52 per cent.). For each gram of protein the average intake of fat was 1.1 grams, and of carbohydrate 4.6 grams. The minerals per unit were: phosphorus, 1.44 grams; calcium, 0.74 gram; iron, 0.015 gram; calcium-phosphorus ratio, 1:1.95; calcium-protein ratio, 1:118. Of the vitamins the B complex was probably sufficient,

¹ *L'Alimentation Rationnelle et les Besoins Énergétiques d'une Population Ouvrière*. By Dr. E. J. Bigwood and G. Roost. With a preface by Ernest Mahaim. Bruxelles: Institut de Sociologie Solvay 1934. (25 fr)

A or D approximately half of standard requirements, C rather more than half, after allowing for loss in cooking. It must be borne in mind that the number of families studied is too small to allow of general conclusions being drawn. This study rather suffers from lack of sequence in arrangement and of clarity in the graphs. There are nearly a hundred tables, many of which need not have been included, while the addition of more tables summarizing the figures would be of great advantage.

VENEREAL DISEASE IN LITERATURE

In a paper read before the Medical Society for the Study of Venereal Diseases, on May 30th,¹ Dr. J. D. Rolleston maintained that in no department of medicine was a knowledge of the lay writers on the history of the subject more necessary than in the domain of venereal disease, inasmuch as the information both of a positive and of a negative character furnished by contemporary writers—poets, dramatists, novelists, and historians—formed a valuable supplement to that derived from the study of the medical works of the time. Systematic investigation of the references to venereal diseases in non-medical literature, side by side with study of the works of medical historians, had been undertaken by numerous professional writers from Astruc in the eighteenth century to Jeanselme at the present day. Dr. Rolleston then gave a survey of the references to syphilis, gonorrhoea, and chancre. Syphilis was first considered under the headings of the Bible, classical antiquity, the Middle Ages, the Elizabethan age, the seventeenth century, the eighteenth century, and modern times. The conclusion reached was that there was no definite description of syphilis in Europe before 1495, whereas subsequently there was an immense amount of literature, lay as well as medical, dealing with various aspects of the new disease. The best-known foreign lay writers on the subject in the sixteenth century were Guicciardini the historian, Erasmus, and Rabelais. Though more than eighty years elapsed before the outbreak of syphilis at the end of the fifteenth century received attention in British medical literature, when William Clowes published his treatise on the venereal disease in 1576, several references to the new disease had appeared much earlier in the Scottish poets William Dunbar and Sir David Lindsay. In the Elizabethan age numerous allusions to syphilis were to be found in Shakespeare, as well as in the contemporary dramatists such as Chapman and Beaumont and Fletcher. The prevalence and severity of syphilis throughout the eighteenth century received mention in numerous non-medical works such as the stories, history, and philosophical writings of Voltaire, the *Mémoires* of Casanova, the novels of Defoe, Fielding, and Smollett, the poems of Swift and Gay, and the letters of Lord Chesterfield. The most remarkable feature of the belletristic literature of the nineteenth century connected with syphilis was that it contained for the first time descriptions of tabs and general paralysis, as shown by the allusions to the former in the works of Heine, Alphonse Daudet, Kipling, and Conan Doyle, and to the latter in Ibsen, Maupassant, and the De Goncourts. The antisiphilic campaign in the French plays and novels at the

beginning of the present century appears to have been inspired by Alfred Fournier. The earliest description of gonorrhoea is that given in Leviticus. From the middle of the sixteenth century gonorrhoea and syphilis were regarded as the same disease, the term "clap" being often applied to the necrotic lesions of tertiary syphilis and "pox" to acute gonorrhoea. The attempts made to prove the existence of syphilis in Europe before the end of the sixteenth century, as exemplified in Beckett's communications to the Royal Society in 1718 and 1721, were due to mistaking the description of gonorrhoea in the mediaeval documents for syphilis. After mentioning literary allusions to gonorrhoea and its complications, Dr. Rolleston maintained that the history of chancre was probably as old as that of gonorrhoea, for it was known in ancient Greece and Rome. The first undoubted description of the disease, however, was given by Palladius in the fourth century A.D. Chancre appears to have been frequent throughout the Middle Ages as well as in classical antiquity, but owing to the identification of syphilis and chancre which took place within six years of the appearance of syphilis in Europe, it was not likely that any distinct description of chancre would appear in non-medical literature.

DRAWING THE G.M.C.

One of the best of the London evening newspapers, if we are rightly informed, has embarked upon a little plan by which it hopes to "draw" the General Medical Council. The idea seems to be to publish in the gossip column, from time to time, paragraphs about medical men of greater or less celebrity, giving their names, ages, addresses, birthmarks, and so forth, in the agreeably intimate manner reserved hitherto for politicians, jockeys, actors and others who court the limelight of the Press. In this way it is hoped to divert the public and to provoke the G.M.C. into taking disciplinary action against the persons named. How long the game will continue we will not venture to predict. Our opinion, for what it may be worth, is that newspaper readers will begin to weary of it in a few weeks' time or less, and (if the analogy will not be taken in ill part) that the catspaws are likely to scratch the monkey before the monkey gets the chestnut.

VISIT OF MEDICAL SECRETARY TO GENEVA

The International Labour Office has lately been considering the question of the economical administration of medical and pharmaceutical benefits under social insurance schemes, and a preliminary consultation on this subject with experts in various countries has encouraged the Office to pursue its inquiry further. A committee of experts will meet in Geneva on July 9th to consider a draft dealing with economical prescribing under sickness insurance schemes, and the Medical Secretary, Dr. G. C. Anderson, has accepted an invitation to sit on this committee as the representative of the British Medical Association.

Sir Frederick Gowland Hopkins, P.R.S., has been awarded the Albert medal of the Royal Society of Arts for 1934 in recognition of his researches in biochemistry and the constituents of food.

¹ To be published in full in the *British Journal of Venereal Diseases*, the organ of the society.

THE IRISH SWEEPSTAKES AND THE HOSPITALS

[FROM A CORRESPONDENT]

A few notes on the twelfth draw conducted by the Hospitals Trust, Ltd., commonly known as the "Irish Sweep," in connexion with the Derby of this year, may prove of interest to those concerned with the conduct of hospitals in Great Britain. The total amount subscribed does not fall far short of three million pounds. Of this approximately £1,800,000 will be expended in prizes. The hospitals receive £519,489, and Government taxation amounts to £173,029. The remainder is absorbed by expenses and promoters' remuneration.

Reviewing the financial question of the Irish sweepstakes to this date we find that, apart from the figures relating to the draw quoted above, the total amount subscribed by members of the public throughout Ireland, Great Britain, and practically every other country over-seas is £30,000,000. Of this amount approximately £20,000,000 has been distributed in prizes. Experience shows that Great Britain has subscribed approximately two-thirds of the total and has received approximately two-thirds of the prize-money. Ireland's subscriptions and prize-money have each been about 7 per cent. of the total.

The Irish hospitals have received, from the first eleven sweepstakes, considerably over £6,000,000; from the latest sweepstakes they will receive, as mentioned above, a further sum exceeding £500,000. It is worth noting that while the first three or four sweepstakes gave assistance solely to the voluntary hospitals of Ireland the Government of the Free State subsequently took power to allocate part of the proceeds to institutions of a non-voluntary character, including the county hospitals, which have played so large a part in Irish Poor Law institutional treatment and accommodation.

At a later date, going a step further, the Free State Government constituted what was, in effect, a new commission, under the Minister of Public Health, to administer the available surplus accruing to the hospitals in general from the sweepstakes. It is this body which will receive and expend the half-million pounds available from the Derby sweepstakes of this year. As an example of the activity of this commission, and the way in which the money may be expended, it may be mentioned that on June 4th the Minister for Local Government and Public Health of the Free State, Mr. S. T. O'Kelly, laid the foundation stone of a £120,000 extension to Mullingar Mental Hospital, which is regarded as a notable advance in the provision of facilities for mental treatment in the Free State. One-half of the amount required has been found by a grant of 50 per cent. of the cost from the Hospitals Trust, through the agency of the Minister. This is an example of the way in which the Hospitals Trust and the relevant Government authorities are utilizing the proceeds of these sweepstakes to provide for increased hospital facilities as distinct from meeting current expenditure.

AN ENDOWMENT-POLICY

The movement which underlies the Irish sweepstakes aims not at meeting only immediate requirements but at providing endowments sufficient to maintain the Irish hospital system for all time. The promoters are not concerned with this year or next year, or the position ten years hence: their object is to ensure that no matter what happens—unless the whole financial structure of Western Europe and America should collapse—the Irish hospitals will be assured at least of a livelihood. That is one aspect of the sweepstakes question which every member of the medical profession in Great Britain should bear in mind. It is not a question of meeting an emergency but of making, so far as is possible, permanent provision for the financing of the hospitals. Lord Powerscourt's remarks at the opening of the Derby draw give a very clear indication of what is in his mind and in the mind of his associates for the future.

It should be noted in this connexion that under the earlier

legislation of the Free State governing these sweepstakes the Derby "sweep" would have been the last of the series, but in the interim legislation has been enacted which makes the system permanent.

A PLAN TO AID RESEARCH

Perhaps the most interesting point in the proceedings was the plea of the Lord Mayor of Dublin (Alderman A. Byrne) that in future some part of the proceeds of the sweepstakes should be earmarked for the finance of research work. In declaring the draw closed, on June 6th, Dr. R. J. Rowlette announced that a definite scheme for the promotion of medical research had been formulated for submission to the responsible Free State Minister. This scheme would provide for research not only in Ireland but in other countries. It would enable the ablest of their young medical men and women to travel to any part of the world in the interests of research. The Irish hospitals had to thank not only the people of Ireland but of every part of the world, and in the research scheme opportunities would be offered not only to Irish workers but to capable ambitious workers from other countries.

In a reference to the progress of the hospitals sweepstakes fund in past years, Dr. Rowlette said that a study was now being made of the whole hospital system of the country, and hospitals might be assured that proper demands would, in due course, be met from the accumulated funds. In the course of the next few years they would have well-built and well-equipped hospitals provided with endowments for the future.

CONGRESS ON LYMPHATISM

Under the presidency of Professor A. B. MARFAN an international congress on lymphatism was held at La Bourbouls on June 9th and 10th. The papers presented at the scientific sessions were numerous, and dealt with many aspects of the subject.

SCIENTIFIC PAPERS

Under the general heading of "Aetiology and Pathology of Lymphatism" the president, Professor Marfan, opened the first day's proceedings with an important communication, in which he indicated the great difficulty he found over defining the term "lymphatism," and he offered as his own view that this word represented a state characterized by a persistent hyperplasia, more or less generalized, of the lymphatic glands and lymphoid tissue, resulting from a generalized reaction by the organs or tissues to the majority of prolonged injections or intoxications. Professor J. TAILLENS (Lausanne), in a spirited address, attacked the use of the term "lymphatism," stating that in his forty years' experience he had never met a case of this disorder. He believed that what was meant in most instances by the use of the word was a state of enlargement of the lymphatic tissue in the nasopharynx with the attendant possibilities of local and generalized infection. The second general division of the contributions was entitled "Forms and Varieties of Lymphatism." Professor P. LEREBOLLET (Paris) dealt with the condition of "status thymico-lymphaticus," affirming that enlargement of the thymus was not an essential part of this syndrome. Professor V. GILLOR (Algiers) discussed the relation between lymphatism and malaria, concluding that the one had nothing to do with the other. Professor E. GÖRTER (Leyden), accepting the view that lymphatism was part of the exudative diathesis of Czerny, brought forward evidence of endocrine disturbances in "lymphatic" children, more especially dysfunction of the adrenals. A study of the blood sugar levels after injection of adrenaline in such children showed less elevation than in normal controls. Dr. ALAN MONCRIEFF (London) briefly explained the current English view, which did not favour the use of the term "lymphatic diathesis," and pointed out that despite the absence of the word "lymphatism" from the medical vocabulary

in Great Britain the common diagnosis of "T's and A's" in reality described very much the same sort of child discussed by Continental speakers. Professor C. COHEN (Brussels) described the campaign in Belgium established to deal with the anaemic, debilitated type of child who required convalescence in the country or at the seaside. The therapeutic aspect of the subject was dealt with in a series of papers grouped under the title "Treatment of Lymphatism." Dr. J. ANGLADA (La Bourboule) indicated the type of malady which would be benefited by a course of treatment at this spa. The waters, rich in arsenic, are drunk, injected subcutaneously or intramuscularly, employed as baths or douches, and used as sprays for the nose and pharynx. In addition, La Bourboule offers special facilities for physical treatment of children in organized heliotherapy, open-air gymnastics, and breathing exercises under medical supervision. Dr. J. HALLÉ (Paris) and Dr. P. FERREYROLLES (La Bourboule) described the results of sending children from Paris to La Bourboule. The public assistance officials of the former city have sent over two thousand children to the spa during the past twelve years, obtaining particularly good results in cases of asthma.

SOCIAL FUNCTIONS

This international congress was organized by the Institute of Hydrology and Medical School of Clermont Ferrand, the Mineral Water Company of La Bourboule, the Medical Society of La Bourboule, and the Municipal authorities of that town. It was attended by approximately 500 visitors, who were guests of the Mineral Water Company at a magnificent banquet at the Casino on the evening of June 9th. Visits were paid to the baths, and to the laboratories and wards of the local hospital, while there were many excursions to places of interest in the district, including the neighbouring spa, Mont Dore.

ROCKEFELLER MEDICAL FELLOWSHIPS

The Medical Research Council announces that, on behalf of the Rockefeller Foundation, it has made the following awards of travelling Fellowships for the academic year 1934-5. These Fellowships are awarded to graduates who have had some training in research work, either in the primary sciences of medicine or in clinical medicine and surgery, and who are likely to profit by a period of work abroad before taking up positions for higher teaching or research in the British Isles.

IAN AIRD, M.B., F.R.C.S.Ed., Demonstrator in Anatomy, University of Edinburgh, and Clinical Tutor in Surgery, Royal Infirmary, Edinburgh.

IAN ALFRED ANDERSON, B.Sc., M.B.Aberd., House-Physician, Royal Infirmary, Aberdeen.

ERIC GORDON OASTLER, B.A.Oxon, M.B.Glas., Professor of Physiology, St. Mungo's College, Glasgow, and Assistant Physician, Royal Infirmary, Glasgow.

WILFRED HARDING OWLES, M.A., B.Sc., B.M.Oxon, Resident Medical Registrar, Queen's Hospital, Birmingham.

HAROLD LEEMING SHEEHAN, M.Sc., M.D.Manch., Lecturer in Pathology, University of Manchester.

CLIFFORD WILSON, M.A., B.M.Oxon, Assistant in Pathology, London Hospital.

All the Fellows appointed this year will work at centres in the United States.

The third edition of the *Official Guide Book of Medical Post-Graduate Work in Hungary* gives a well-illustrated account of the various facilities which this steadily growing country offers for advanced medical training. There are four university centres—namely, at Budapest, Szeged, Pécs, and Debrecen. Medical practitioners from other countries are welcomed as students, and detailed information of the various courses of instruction and other opportunities available are obtainable from the headquarters of the Hungarian Medical Post-Graduate Committee, Maria-utca 39, Budapest. A post-graduate course for American practitioners has been arranged for September 10th to 15th.

Scotland

Changes in Glasgow Medical Faculty

At a meeting of the University Court of Glasgow University, held on June 14th, with the Principal, Sir Robert S. Rait, presiding, it was intimated that Professor Munro Kerr would relinquish the Regius chair of midwifery, and Professor Walter K. Hunter the Muirhead chair of medicine, from September 30th next. The Secretary of State for Scotland has announced that applications for the office of Regius professor of midwifery must be sent immediately, with copies of two recent testimonials, to the Private Secretary, Scottish Offices, Whitehall, London, S.W.1.

Welfare of the Blind

The annual conference of the Scottish National Federation for the Welfare of the Blind was held in Aberdeen on June 14th and 15th, and delegates numbering about 200 were received at a civic reception in the town and county hall. Mr. W. R. Halliday, Glasgow, in opening a discussion on the prevention of blindness, recalled that the Federation had been founded ten years ago at Aberdeen. He believed that in Scotland they were far ahead of other countries in the correct certification of blindness. The State was interested in prevention, since it could not afford to lose the potential productivity of any of its citizens. Industrial workers were continually exposing themselves to serious eye dangers, and people were constantly using the naked eye for work which demanded the use of glasses, while others failed to get proper advice and treatment in the early stages of eye disorders. A vigorous campaign of enlightenment, therefore, would be of great advantage to the community. He suggested that a Prevention of Blindness Committee for Scotland should be set up. Mr. C. H. W. Anderson, Edinburgh, said that such a committee ought to be named the Preservation of Sight Committee. A pamphlet on the care of the eye had been prepared by Dr. George Mackay, and distributed to the number of 20,000, and an illustrated leaflet, of which 14,000 copies were circulated, had been published by the Federation. In the course of the discussion the practice of purchasing cheap spectacles was condemned as detrimental to eyesight. On the second day of the conference Mr. William Edgar, president of the Fife Society for the Blind, read a paper on salesmanship by the blind. He said that most societies could give instances of blind persons earning their livelihood by the sale of goods. If this was to be a success, however, training must be practical and theoretical, and efficiency must be promoted by printing receipt slips, bill-heads, etc., in Braille. Captain J. Bell Cumming, Dundee, said that institutions in Scotland were at present finding full-time employment for about 1,000 blind persons, but he believed that salesmanship by the blind was beyond practical politics. At the annual business meeting it was agreed that the model scheme under the Blind Persons Act, 1920, should be sent to all affiliated bodies for their approval.

Care of Scottish Mental Defectives

At the recent conference in Edinburgh of the Scottish Association of Mental Welfare various problems of mental deficiency were discussed. Lord Polwarth said that there was no more difficult question at the present day than that of mental deficiency, and in Scotland they were conscious that there was a lack of accommodation for mentally deficient cases. Dr. M. Hamblin Smith, late superintendent of Birmingham Prison, in a paper on "The Medical Examination of Offenders," said that the most diverse

estimates had been made as to the percentage of delinquents who came within the definitions given in the English Mental Deficiency Acts. These varied from 90 per cent. down to statements made by the managers of reformatory institutions that there were no mental defectives among their inmates. Both of these extremes came from America, but the speaker thought that most workers on this subject would agree that not more than 5 per cent. of delinquents were mental defectives, and that probably 3 per cent. was nearer the truth. He urged that in cases in which mental abnormality was suspected in an accused person the case should be adjourned until the question of the accused's mental condition had been settled. Probation was so easy and apparently so good a mode of disposing of cases of delinquency that resort was often made to it without due consideration of the accused person's mentality. Probation should, however, be made a serious affair, and should always be combined with measures of social rehabilitation. An apparently trivial offence might contain the germ of future difficulties of the utmost moment. Modern students of crime were often accused of wishing to pamper offenders, and it might be that many offenders would prefer to continue the present rough-and-ready measures, but the protection of society was the primary consideration. It would be an advantage, the speaker believed, if there were a psychological assessor in every criminal court. Professor James Drever said that he agreed that the problem of the offender was a psychological one, but at present there were not enough experts to carry out the psychological investigation required in all cases, and the general medical practitioner could not be expected to undertake mental examination any more than to perform a major surgical operation. He believed that more training in psychology and psychiatry should be given to medical students. Dr. W. A. McAllister said that he disagreed with those psychologists who traced everything back to some incident in childhood, for it was very often unnecessary to go far back for an explanation of some misdemeanour.

The High-grade Defective

At the afternoon session a discussion took place on the high-grade mental defective. Dr. W. G. Sym, who presided, said that by the high-grade defective was meant a person who might technically come into the category of feeble-mindedness, but bordered closely on the normal. Such a person did better when boarded out than when placed in an institution, but so long as he was not injurious to others or to himself there was no reason for any segregation. Dr. D. J. Forbes of Baldovan Institution, Dundee, said that at least 8 per 1,000 of the population belonged to the mentally defective class, but of these some 75 per cent. belonged to the higher-grade class. Accordingly the training of higher-grade defectives was a problem of much importance. The quiet and docile type was apt to find his way into an institution owing to unfortunate environment at home or incapacity for education, while the restless, unsettled type who fell into mischief was found in the delinquent class of the outside world. At the age of 16 a number of both classes were discharged from institutions, with a view to earning at least part of their own living and still having protection and supervision, and, when possible, the benefit of the After-Care Association. Dr. Kate Fraser (Edinburgh), dealing with boarded-out defectives, said that many were capable of carrying out useful work in community organizations. Last year over 1,000 certificated defectives were boarded out under guardians who were not relatives. The best type of home for defective boys was the small farm, where they worked in the fields along with the guardian. The girls were best placed in country cottages

or in village communities, doing work in gardens or on farms. Under these conditions the mental defective was treated as an ordinary human being, but success in this method of dealing with the mental defective depended upon patience and sympathetic understanding of the guardians. Miss Carmen Service (Paisley) discussed the relation of high-grade defectives to the community, and said that the friendly supervision of local care committees was most important. It had been found that the high-grade defective was well suited to take up work of a routine nature which was monotonous to those of higher intellect. The question of hostels for high-grade defectives deserved consideration, for the hostel was a useful step between an institution and the demands made by life in the community, and it was better than an unsuitable home.

England and Wales

The Harveian Society

The Buckston Browne annual dinner of the Harveian Society of London was held on June 14th in the Connaught Rooms under the chairmanship of Sir Buckston Browne, F.R.C.S., life-president of the society. The guests included the medical heads of the three Services, the President of the Royal Academy, the Regius Professor of Physic at Cambridge, the President of the Royal Society of Medicine, the President of the British College of Obstetricians and Gynaecologists, and the Editors of the *Lancet* and the *British Medical Journal*. After the loyal toasts had been honoured "The Society" was toasted by the Greek Minister, M. Demetrius Caclamanos, who expressed his delight at meeting members of a profession whose patron saints were Aesculapius and Hippocrates, and at enjoying the hospitality of a society founded in honour of the great English exponent of the Greek spirit in science. The chairman, in reply, thanked His Excellency for a charming speech seasoned with Attic salt. He himself, Sir Buckston said, was presiding on this occasion as the representative of the real president, Dr. Hope Gosse, who, though not able to be with them that night, was making a good recovery from his serious motoring accident. The society now numbered nearly four hundred members, and was full of life and vigour. William Harvey understood the value of professional intercourse, and would therefore have rejoiced in the discussions and banquets of the Harveian Society. Looking back over a long life, Sir Buckston Browne noted, with especial pleasure, the steady advance of the medical profession in social esteem. Mr. A. Dickson Wright, who proposed the health of the visitors in graceful terms, said that the Buckston Browne dinner was becoming one of the medical events of the year, and mentioned that their host and chairman was now celebrating the diamond jubilee of his entrance into the profession. Dr. F. M. R. Walshe, the Harveian lecturer, responded briefly in light vein. The Englishman's adulation of the amateur, he said, had gone so far that the expert was everywhere becoming an object of derision; magic and manipulation had to-day an unequalled opportunity. Mr. F. R. Mortimer, Master of the Barbers' Company, who also responded, touched on the long association, which came to an end in 1745, between surgery and the barber's craft.

The Drought: Emergency Measures

On June 13th the Minister of Health conferred on the question of urban water supplies with members of the Standing Conference on Water Supplies, whose representatives are drawn from various parts of the country. In welcoming the members Sir Hilton Young said that he had called them together to assist on questions arising

out of the drought. The objects in appointing the conference were to secure first-hand information of conditions, to enable him to assess the difficulties to be encountered, and to prepare measures for overcoming the difficulties. The conference gave a review of the position, which showed that, generally, conditions in the towns were fairly good considering the continued absence of rain. In some towns reserves were very low, but there was no reason to think that the water undertakers would not be able to meet the situation, if consumers played their part, with the aid of special additional powers for increasing supplies and improving distribution now readily obtainable under the Water Shortage Act passed last month. The relatively good position in the towns is due in large measure to the economies effected with the co-operation of consumers. In the area of the Metropolitan Water Board a reduction in consumption of over 10 per cent. has been effected by voluntary economies. There is, however, plenty of room for larger reductions, and efforts in this direction must not be relaxed, otherwise difficulties may ensue later in the summer and autumn which can be avoided if reasonable care is taken now. At some places substantial economies have been effected in trade, as well as in domestic consumption, without any curtailment of supplies needed for trade, which it is important to avoid, and where necessary water undertakers can assist by suggesting ways by which waste may be prevented. The following matters were referred to for more general attention. Water undertakers should keep the public informed in clear and simple terms about the manner and measure of the economies in the use of water required by the local conditions. At some places marked savings have been effected by the loan of qualified waste inspectors from large water undertakers to neighbouring small undertakers. Substantial savings can be effected by transport undertakings and private owners in washing cars. Attention was called to the economies that could be effected by public authorities in the use of water for such purposes as street washing and watering in public parks.

Out-Patient Time-Tables at London Voluntary Hospitals

Arising out of the inquiry conducted by a special committee into out-patient methods in the London voluntary hospitals, King Edward's Hospital Fund has published a revised edition of the Hospital Out-patient Time-table, giving information which, it is hoped, will be useful in preventing the waiting, with possible resulting hardship, which occurs when patients attend hospital out-patient departments at the wrong hour or even on the wrong day. This time-table, which has been revised to May, 1934, sets out the hours at which medical, surgical, and other special cases are dealt with at the various hospitals in the King's Fund area (within a radius of eleven miles from St. Paul's). It should be of assistance not only to general practitioners who may wish to send their patients for consultations, but also to the various social agencies, by whom the actual arrangements for the attendance of out-patients at hospital often have to be made. The time-table, which can either be kept folded as an octavo booklet or unfolded in quarto form and inserted in a telephone directory, may be obtained free of charge from Messrs. Geo. Barber and Son, Ltd., Fumival Street, E.C.4.

Cancer Research

In March, 1933, the International Cancer Research Foundation, established by Mr. William H. Donner of Philadelphia, awarded £1,000 per annum for a period of two years to the Research Institute of the Cancer Hospital (Free), London, in support of investigations into factors which underlie the origin of malignant growths. This grant has provided two research scholarships, which are

held by Mr. G. A. D. Haslewood, M.Sc., who is working with Dr. J. W. Cook in the Research Institute, and by Miss Edna Roe, B.Sc., who is studying the molecular structure of carcinogenic compounds by physical methods. Miss Roe is working under Dr. Mayneord, in the physics section of the radiological department of the Cancer Hospital. The grant has also defrayed a part of the cost of this work. Under the direction of Dr. Cook, Mr. Haslewood has recently prepared a very active cancer-producing compound, methylcholanthrene, from another compound, deoxycholic acid, which is known to occur in the human body. To assist in further developments of this work the trustees of the International Cancer Research Foundation have now decided that this grant shall be continued for an additional three years, until June 1st, 1938.

Ireland

Restoration of the "Cut" in Northern Ireland

The Chairman (Dr. D. Gray), the vice-chairman (Dr. R. Henry), and the secretary (Dr. S. E. A. Acheson) of the Central Practitioners' Committee of Northern Ireland recently had an interview with the Minister of Labour (the Right Hon. J. M. Andrews), who acts as Minister of Health for Northern Ireland. They put before him the claims of insurance medical practitioners in Northern Ireland to be treated similarly to their colleagues in Great Britain. At a subsequent meeting the Minister said he was pleased to be able to inform the deputation that half of the "cut" would be restored as from July 1st. A similar concession would be granted to the chemists.

Coombe Lying-in Hospital, Dublin

The clinical report for 1933 of the Coombe Lying-in Hospital, Dublin, is, as usual, mainly statistical. In the twelve months 1,430 patients were admitted to the maternity department, and of these 1,279 were delivered in hospital. This represents an increase of twenty-seven admissions and a decrease of nine deliveries in comparison with the figures of the preceding year. Overcrowding in the hospital has become a most serious problem, and in 1933, probably for the first time in the history of the institution, it was found necessary to refuse admission to about thirty women, many of them already in labour, owing to lack of a vacant bed. In some of these cases nurses and students returned home with the patients to conduct the confinements. For others accommodation was found in the Rotunda and the National Maternity Hospitals. No attempt has been made in the report to separate booked from emergency cases. It is argued that such a distinction is not justly applicable to the Coombe Hospital patients, most of whom are taken in without ceremony on their own request. When patients have attended the pre-natal clinic this fact is noted in the report if it appears to be relevant. There were nine deaths last year, and the B.M.A. morbidity rate was 2.1 per cent. A change was made throughout the year in the conduct of normal deliveries, the birth of the head being permitted without any intervention. This practice, it is stated, has led to an increase of 6 per cent. in the frequency of perineal tears. It is, however, thought to be worth a more extended trial, since its introduction coincides with the lowest morbidity rate yet recorded in the hospital. Perineal lacerations numbered 249; of these 187 occurred in primiparae, four being complete. In the extern department 1,517 patients were delivered, an increase of thirty-seven over the figure for the previous year. Perineal tears were recorded in ninety cases. There were 478 admissions to the gynaecological department; palliative treatment alone was required in ninety of these cases, and radium was used in eight instances.

estimates had been made as to the percentage of delinquents who came within the definitions given in the English Mental Deficiency Acts. These varied from 90 per cent. down to statements made by the managers of reformatory institutions that there were no mental defectives among their inmates. Both of these extremes came from America, but the speaker thought that most workers on this subject would agree that not more than 5 per cent. of delinquents were mental defectives, and that probably 3 per cent. was nearer the truth. He urged that in cases in which mental abnormality was suspected in an accused person the case should be adjourned until the question of the accused's mental condition had been settled. Probation was so easy and apparently so good a mode of disposing of cases of delinquency that resort was often made to it without due consideration of the accused person's mentality. Probation should, however, be made a serious affair, and should always be combined with measures of social rehabilitation. An apparently trivial offence might contain the germ of future difficulties of the utmost moment. Modern students of crime were often accused of wishing to pamper offenders, and it might be that many offenders would prefer to continue the present rough-and-ready measures, but the protection of society was the primary consideration. A similar concession would be granted to the chemists.

Coombe Lying-in Hospital, Dublin

The clinical report for 1933 of the Coombe Lying-in Hospital, Dublin, is, as usual, mainly statistical. In the twelve months 1,430 patients were admitted to the maternity department, and of these 1,279 were delivered in hospital. This represents an increase of twenty-seven admissions and a decrease of nine deliveries in comparison with the figures of the preceding year. Overcrowding in the hospital has become a most serious problem, and in 1933, probably for the first time in the history of the institution, it was found necessary to refuse admission to about thirty women, many of them already in labour, owing to lack of a vacant bed. In some of these cases nurses and students returned home with the patients to conduct the confinements. For others accommodation was found in the Rotunda and the National Maternity Hospitals. No attempt has been made in the report to separate booked from emergency cases. It is argued that such a distinction is not justly applicable to the Coombe Hospital patients, most of whom are taken in without ceremony on their own request. When patients have attended the pre-natal clinic this fact is noted in the report if it appears to be relevant. There were nine deaths last year, and the B.M.A. morbidity rate was 2.1 per cent. A change was made throughout the year in the conduct of normal deliveries, the birth of the head being permitted without any intervention. This practice, it is stated, has led to an increase of 6 per cent. in the frequency of perineal tears. It is, however, thought to be worth a more extended trial, since its introduction coincides with the lowest morbidity rate yet recorded in the hospital. Perineal lacerations numbered 249; of these 187 occurred in primiparae, four being complete. In the extern department 1,517 patients were delivered, an increase of thirty-seven over the figure for the previous year. Perineal tears were recorded in ninety cases. There were 478 admissions to the gynaecological department; palliative treatment alone was required in ninety of these cases, and radium was used in eight instances.

Reports of Societies

PREVENTION OF TUBERCULOSIS

ANNUAL CONFERENCE IN LONDON

The twentieth annual conference of the National Association for the Prevention of Tuberculosis was held on June 14th and 15th, in the Conference Hall of the London County Council, under the chairmanship of Sir ROBERT PHILIP. Since the national scheme for the prevention and control of this disease had been originally based on the recommendations of the Departmental Committee on Tuberculosis (1912-13), the proceedings were directed mainly to a review of the experience gained during twenty-one years.

Lord SNELL (Chairman of the London County Council) welcomed the conference, the work of which, he said, was of supreme social importance. London had now abolished any waiting by applicants for tuberculosis treatment. The selecting of some of the parks' staff from members of the Burrow Hill Colony had proved a great success.

Sir HILTON YOUNG, Minister of Health, paid a warm tribute to the work of the National Association, since its inauguration in 1898, in marshalling and instructing public opinion. Voluntary efforts had brought into being the first dispensaries and sanatoria. Then had followed the provisions in the Insurance Act for tuberculous insured persons, and the adoption by the Government of the findings of the Astor Committee. He reviewed the progress that had been made, and expressed regret that there was still much too great a tendency to ignore the early symptoms. There had been many factors concerned in the greatly reduced incidence of tuberculosis, but he was convinced that there would be no final success in the campaign against the disease until its slum breeding places had been eradicated.

EXPERIENCE OF TWENTY-ONE YEARS

Lord ASTOR (Chairman of the Departmental Committee on Tuberculosis) reviewed the history of the last twenty-one years, beginning with a reference to the work of that very composite body, which had from the first been much concerned with the respective merits of rival forms of treatment. Its recommendations, owing to the outbreak of war, had been stopped from coming into effect until 1919-21. The importance of prevention had been emphasized from the start, and many health measures in industry and elsewhere had owed their origin to the stressing of this outlook. Although over 40 per cent. of cows were infected, the number yielding infected milk was only 2 per cent., but about 5 per cent. of human tuberculosis was traceable to this cause. Some of the decline in the incidence of the disease in children was attributable to preventive measures in this sphere. Further improvement as regards the milk supply was rather retarded by differences of outlook in certain Government Departments. There were too many brands of tuberculin of differing potencies on the market, but all were at present recognized officially for testing purposes. There was also a variability as regards the skill of different veterinary practitioners, and so their results were not fairly comparable always. Standardization of tuberculin was an urgent need, with restriction to the employment of one type. Research had made great advances, and had been kept free from any departmental control.

Dr. A. SALUSBURY MACNALLY (senior medical officer, Ministry of Health) contributed details from the public health and medical aspects. After publication of the report of the Departmental Committee, and the then Local Government Board had begun to bring the recommendations therein into effect, the chief problem was found to be the provision of residential institutional accommodation. The outbreak of war arrested progress temporarily, but at its end the work was continued and extended. At present the obvious field for activity was the instruction of the general public as to the early signs

and symptoms of tuberculosis. The State had realized the existence of complex factors favouring the disease, such as certain forms of occupation, malnutrition, overcrowding, and bad sanitary environment, and it was appreciated that all measures directed towards the health and improvement of the nation generally were important contributions toward the prevention of tuberculosis. Anti-tuberculosis work was now regarded as an integral part of public health, and the medical officer of health could marshal and co-ordinate all branches of the service in the prevention of the disease. Every advance in treatment and all proved methods of therapy were brought to the notice of local authorities and their medical officers. Still more attention needed to be paid to the examination of contacts, and to the provision of adequate after-care for cases of arrested disease, with special reference to home surroundings and occupation.

Dr. N. D. BARDSWELL (principal assistant medical officer, L.C.C.) reviewed the treatment of tuberculosis in London since 1913, with special reference to the way in which all the existing efficient agencies, both voluntary and official, had been augmented and fitted into a comprehensive scheme. This now comprised a central co-ordinating authority at the County Hall which provided residential treatment, and thirty-five dispensaries in the various London boroughs linked up with neighbouring hospitals. A decline of nearly 40 per cent. in pulmonary tuberculosis, and of over 75 per cent. in non-pulmonary tuberculosis, from 1911 to 1933 was striking evidence of the improvement that had resulted. Although other factors were concerned in this falling incidence, which had, indeed, been observable since 1875, he believed that the special efforts directed towards the prevention of tuberculosis during the past twenty-one years had materially contributed to the diminution of the disease. In that period no body of sick persons in London had gained so much as those suffering from tuberculosis. The high ideal set before public authorities in 1913 that no tuberculous person in their areas should be unknown to them, or be without the opportunity of skilled advice and treatment, had been achieved in London. Collapse therapy had effected some remarkable successes, but necessitated a high degree of skill. It had not yet affected the statistics of the ultimate results of treatment, and was certainly not suitable for general use. The popularity of tuberculin treatment had gradually faded away, and was not to-day seriously considered as a cure. Boarding out of two groups of children was practised—namely, those living under specially dangerous conditions as regards infection, and those who would be left unattended if the woman of the household went away for treatment. The number dealt with thus each year was about 200. Of about 3,500 beds maintained by the London County Council for the treatment of tuberculosis, 1,500 were in institutions outside its own jurisdiction.

Sir JOHN ROBERTSON (professor of public health, Birmingham) emphasized the point that much more could yet be done to reduce the number of new cases. Statistics showed that the mortality from all forms of tuberculosis was 2½ times as great among the unskilled as among the middle class, and that the mortality among the skilled artisan was nearly double that in the upper and middle classes. More instruction should be made available, and much greater care should be taken of contacts than was the case at present in some areas. Young contacts should be kept under observation for as long as five years, and facilities be available for those who needed special treatment. Home visits were essential in these cases. Many industries employing young persons might be brought under the purview of the Home Office with a view to getting better conditions of work established. Clerks and shop assistants, who did not come under the Factory Acts, might with advantage be included for the purpose of tuberculosis prevention. It did not seem to be beyond the power of the present factory organization to require a health certificate of fitness to enter a particular employment. If there was found an undue incidence of the disease among those who had been healthy on entrance, some liability under the Workmen's Compensation Act would soon bring into operation improvement in the conditions of work.

THE TUBERCULOSIS DISPENSARY

Dr. G. LISSANT COX (central tuberculosis officer, Lancashire County Council), opening a discussion on the place and uses of the tuberculosis dispensary, said that this was essentially not a building but an organization made up of many factors, of which the human factor was not the least important. The dispensary unit should work in unity with the institutional unit, and it was the lack of this unity which was the real reason of much of the prevailing ineffective work. In London there were two controlling authorities—the metropolitan borough and the county council—where there should only be one. Further, administrative changes required to be made so that the tuberculosis officer should be at one and the same time a medical superintendent, visiting or resident, and the medical superintendent be in part a tuberculosis dispensary officer. He would thus see as a whole the complex problem presented by each patient, and consult with the family doctor. When first brought into being, dispensary units had been much too small, and this had probably been the cause of an unnecessarily low and ineffective standard of work. The size of a dispensary unit, measured by the population it served, should be about 200,000 in a rural area and 300,000 in an urban district. The very small local authorities of 50,000 to 100,000 population should combine for dispensary and institutional work. Each unit must have an x-ray plant available, and the tuberculosis officer should be able to interpret his own skiagrams. There must also be a room for artificial pneumothorax refills, and at the larger dispensaries a room or rooms for an artificial light clinic. The unit should be large enough to necessitate a graded staff.

Dr. D. MELVILLE DUNLOP (department of tuberculosis, Edinburgh) thought that in many instances the dispensary hours were too short and too crowded with work. Inflated attendances should be discouraged, and chronic bronchitic and asthmatic patients discharged. Secretarial assistance was often inadequate. The banding together of small dispensary units should be hastened. Treatment should be of a specific and not of a symptomatic kind. The tuberculosis officer should, however, be not only a clinician, but also a supervisor of public health requirements, the claims of the individual patient not being over-stressed to the exclusion of the claims of the community. The examination of contacts, and particularly of contact children, was one of the most important functions of the dispensary in the prevention of tuberculosis. Interviewing of the family enabled useful readjustments of the mode of life to be suggested. It was said that the dispensary and the school medical service were so often segregated in watertight compartments, with little or no interrelation. Medical students might well attend in order to study the tuberculosis problem as it occurred in real medical practice.

In the general discussion which followed it was suggested that the dispensaries ought to be attached to the teaching and public assistance hospitals, tuberculosis officers looking forward to clinical rather than administrative preferment. Dr. J. G. WILSON of Cardiff thought that each of the three dispensary schemes did well in suitable areas. He had had personal experience of the excellent work of the Lancashire scheme, but the small unit of 54,000 had a specially intimate touch and good co-ordination, which he had found commendable apart from the admitted financial difficulties. The Welsh National Memorial was a magnificent machine, but lacked the personal touch. Other recommendations were the paying of more attention to signs of under-nourishment in contacts even in the absence of suspicious signs and symptoms, the reduction of hours of work in dust-laden atmospheres, and the substitution of the terms "dispensary" and "tuberculosis officer" by "chest or health centre" and "tuberculosis physician."

RESIDENTIAL INSTITUTIONS

Dr. JAMES WATT (medical superintendent, King George V Sanatorium, Godalming) opened a discussion on residential institutions by pointing out how great a change had been brought about in them by the big strides made in radiography of the chest and the advances in collapse therapy.

The work of an up-to-date chest hospital or sanatorium now revolved round its x-ray department. The consequent demonstration of pleural adhesions preventing satisfactory collapse of the diseased lung had led to the development of thoracoscopy, and the cutting of adhesions by electric currents. In a modern sanatorium collapse therapy was undertaken in from 20 to 50 per cent. of the cases. The sanatorium no longer resembled a convalescent home but a hospital; whereas formerly about 20 per cent. of the patients were confined to bed, it was now common to find only about 50 per cent. ambulant cases. One nurse to six beds was usual, and the cost had advanced from the Departmental Committee's estimate of £150 per bed to £500 or £700. Earlier and more frequent surgical intervention was now usual, and thoracoplasty, the most drastic form of collapse therapy, offered an almost equal chance of recovery to patients who under the old methods had no more than a one in four or one in five chance of survival. With this change in outlook, the sanatorium was now preferably situated on the outskirts of a town, easily accessible to visiting consultants. In addition to treating in-patients, it should be the centre for diagnosis, have an out-patient department for pneumothorax refills, and take over dispensary functions, including after-care. Dr. Watt thought that these changes had rendered the sanatorium a far more effective weapon against tuberculosis than it had ever been, and that its outlook for the future was very promising.

Dr. R. C. WINGFIELD (medical superintendent, Brompton Hospital Sanatorium, Fimley) thought that now in 1934 the old-style sanatorium was no longer the main treatment centre, but rather a polishing and testing centre where, under skilled supervision, the patient was tested and trained for his return to the stresses of everyday life, or was sent back to the hospital bed for more energetic treatment if required. There was no uniformity of sanatorium work in this country. In some areas, as in London, there were large sanatoria each designed for a particular type of case, serving the institutional needs of several districts, and working under an authority different from that of the dispensaries which they served. This divorce of sanatorium from dispensary treatment was very unsound. In Wales there was the same system, but the inclusion of sanatoria and dispensaries under the one authority allowed surer co-operation. In Surrey one large central institution was utilized more or less for all types of case, and was under the same authorities as were the dispensaries. Some sanatoria served more than one county, while the older proprietary institutions treated cases for many local authorities by private arrangement, and had no official relations with the dispensaries. Finally, the Lancashire method tended to multiply smaller institutions, but linked them as closely as possible with the dispensaries, in some cases placing both under the same medical officer. The independence and pre-eminence of the old-style sanatoria had been mistakenly perpetuated in most developments of the national tuberculosis scheme. This life-long disease was not cured by collapse therapy or sojourn in a sanatorium, and the dispensary, with its field work, must be the chief unit of a successful service. The present general tendency to starve the dispensaries financially for the benefit of the sanatorium was as unsound scientifically as it was practically uneconomic. At least as much money must be allocated by the public authority to its dispensary as to its institutional service.

Dr. J. B. McDougall (medical director, British Legion Village, Preston Hall) said that in the past too much attention had been paid to the purely medical aspects of tuberculosis and not enough to the important economic considerations. The failure of after-care committees in many parts of the country had been due to lack of financial support. After-care, using the term in its widest sense, had made less progress in efficiency than any other branch of the anti-tuberculosis scheme. The village settlement, as exemplified at Papworth and Preston Hall, where about £200,000 worth of goods was sold annually to the public, and approximately £50,000 was paid in wages to ex-patients, might be regarded as the ideal, but local authorities had been deterred in many cases by

financial considerations. There were many posts in sanatoria which could well be filled by ex-patients. Why should after-care schemes be condemned as uneconomic when this condition was not imposed on sanatoria? Without prolonged treatment it was impossible to obtain good results in at least half the cases. In the village settlement the family as a whole was cared for as carefully as the patient. The time had come for an organization like the National Association for the Prevention of Tuberculosis to place before local authorities, not one scheme, but the choice of one or more of a large number of schemes which had been successful in this and in other countries.

Dr. F. R. G. HEAF (medical superintendent, Colindale Hospital, Hendon) believed that tuberculosis hospitals should be situated near large towns, and be able to accommodate early febrile cases requiring rest in bed, cases needing special treatment, particularly major surgical operations; advanced cases with some prospects of improvement; and a certain number of hopeless cases. They should also be centres for research work. A unit for thoracic surgery became more efficient and economical the more it was used. These hospitals should therefore be used for the treatment of all forms of chronic pulmonary diseases, and it was a bad policy to send all advanced cases to one institution. Patients requiring routine rest and exercises should not be kept at a tuberculosis hospital, but centres of occupational therapy should be established at hospitals and in towns near to patients' homes. The establishment of rest homes for advanced cases with unsuitable homes of their own was recommended, some form of employment being provided. The ambulant advanced case was more dangerous to the community than the bed-ridden one.

CO-ORDINATION IN A TUBERCULOSIS SCHEME

The co-ordination of the several elements in a tuberculosis scheme was discussed by Dr. H. P. NEWSHOLME (medical officer of health for Birmingham), who said that in that city there had been no difficulty two years ago in charging the chief clinical tuberculosis officer with all aspects of tuberculosis work, including the control of statistical and other clerks, and of nurses previously under a general administrative officer, as well as the regulation of inspection of home conditions. The link with the general health activities of the city had been effectively forged by a regular weekly conference between the medical officer of health and the chief tuberculosis officer, and by contact between the latter and other officers engaged in administration as occasion arose. Action in regard to defective housing and the provision of better accommodation was followed up by the administrative staff, on receipt of information sent in by the tuberculosis department. In Birmingham the tuberculosis service had been welded into a unit which was unusually self-controlled and adjusted. Linked up with this was the high degree of co-ordination between the dispensary in its capacity as clearing-house and the beds for sanatorium and hospital cases, for children, for observation cases, and for surgical tuberculosis, as well as for the transfer of tuberculous patients to and from general and special hospitals, whether municipal or voluntary. The occupational scheme was established at the central sanatorium. The home conditions were reported directly to the dispensary, and housing defects were remedied through the general public health department; better housing was acquired through that department and the estates department, and shelters or hedging were distributed through the hospital steward's section of the public health department. Extra food was provided by special arrangements with food tradesmen, and monetary and other assistance by the public assistance department. Details were given of the close liaison built up between the tuberculosis work and the maternity and child welfare service, and also of the arrangements with the school medical service. Similarly good relations existed with general practitioners and the managements of the voluntary and municipal hospitals.

AFTER-CARE

A comprehensive account of the duties and possibilities of after-care was contributed by Miss EDITH MCGAW (honorary secretary, Paddington Tuberculosis Dispensary), who insisted that the care committee was as much an integral part of the tuberculosis dispensary as the dispensary was of the national scheme. Yet there were only about 150 care committees in the country in comparison with 750 dispensaries. Tuberculosis was a many-sided social problem as well as a medical question. The family, not the individual patient, was the unit. The re-creation of that family's home was as essential as the treatment of its members. Miss McGaw described the organization of the care committee, which she thought should preferably be small. Its members could give much help in the homes, including instruction about the cooking of food and the amount of clothing desirable. Outfits could be provided for patients proceeding to sanatoria, incomes augmented, and suitable employment found. Assistance for a time was often needed as regards the home work, and handicraft classes could be encouraged. A wider realization of the value of voluntary workers would have promoted the establishment of care committees, and brought nearer the day of the ending of tuberculosis.

Illustrations of the value of after-care in the Highlands were given by Miss A. E. WHITE, a nurse commissioner on the staff of the National Association.

CORRESPONDENCE

Endocrines—Fact and Fancy

SIR,—The departing steps of the postman coincide with the rustle of masses of falling envelopes; the recipient rapidly separates the obvious wheat from the chaff, the latter being without delay excreted into the suitable receiver. Only occasionally, as, for instance, when a dividend warrant has recently gone astray through not being marked distinctly enough on the outside "Not a circular," does the disillusioned victim inspect the ground-bait. Among the glut of prospectuses, appeals from hospitals, specious and insidious insurance propaganda, puffs of spas from home and abroad, and offers of samples of the "Stop me and try one" type, one cannot fail to be struck by the prevalent scientific journal issued by the big drug firm.

To what extent the profession is influenced by this type of publication as a form of post-graduate education is not for me to say, but at least it must be admitted that the thing is well done. Below a competently extracted account of Bosky's paper on the treatment of nervous affections of the urinary tract is a footnote to the effect that "Quieto" is the ideal sedative for spasmodic conditions; the reviewer of Jones-Robinson's monograph on gallstones casually mentions "Cholestero" as the perfect solvent of biliary concretions.

The preceding fiction is no exaggeration of the art at its most blatant. The more insidious form is found in the modern endocrine advertisement: here, indeed, is an appeal to scientific instincts and measured judgement. Such best-sellers as "Recent researches in endocrinology state—," "Every well-informed practitioner knows that—," "The modern treatment of — recognizes to the utmost the importance of taking into account endocrine influences," "The correlation of endocrine functions," etc., jostle each other in just the same way as do the established clichés of ordinary commercial advertisement. There is appropriate genuflection to every article of the creed. In the case in point, however (the endocrine preparations available to the up-to-date practitioner), there cannot be the slightest doubt.

The use of the extract of whatever gland is vouched for by Drs. A to Z (decorously concealed, of course, in deference to the G.M.C.), who have subjected it to rigorously conducted clinical trials in "this type of endocrine dysfunction," in "a series of cases of hormonal dyscrasia," "instances of glandular hypofunction," etc.; the unnamed investigators, with all scientific reserve and due reticence, even with obvious initial scepticism, report "Good results," "Appreciable improvement," and "Definite amelioration."

Of one particular aspect of glandular failure let there be not the least misgiving. In instances of middle-aged debility in the male, sometime neurasthenia, sometime "failure of gonads," occasionally starkly "impotence," the help is positive and unquestionable (shade of Brown-Séquard!), and there is quoted evidence from M.R.C.S., L.M.S.S.A., M.D., F.R.C.S., and even F.R.C.P., that aid is to hand for those with shirking endocrines. The scientific undercurrent is obvious, and combination of endocrines is the keynote. "Orchitic extract" (why from inflamed testicles?) is skilfully blended with correlated glands. One cannot fail to be touched by the obvious concern with which one firm refers to the way in which the "stresses of the winter" act upon the medical man, and suggests that a combination of testicle and adrenal, at a specially reduced rate for the profession, clearly meets the indications of the case. (It may here be noted sympathetically that the expense and care involved in putting up these preparations preclude the supply of clinical samples, which in any case are unnecessary, as the efficacy of the preparation has been demonstrated beyond doubt. Nevertheless, that the cost question is adequately understood as a barrier is evidenced by the announcement that "owing to increased consumption it has been found possible to reduce the cost of the series of 'umpteenth' injections necessary to obtain satisfactory clinical results from fifteen to twelve guineas.")

It is impossible to deal fully with the subject in the space available, but two other instances may be alluded to. There are, for example, parathyroid extracts. Their field of usefulness is widely indicated as ranging from paralysis agitans, chorea, and epilepsy, through colitis and duodenitis, to chilblains and varicose ulcers. There can again be no hesitation: there are favourable comments from Dr. M, from Dr. N there is enthusiastic support, and Dr. O has employed them with great benefit. Curiously, the preparation is an excised gland for oral administration, by which route it is utterly inert! Finally, there are the baffling patients in whom our "practitioners even of long experience" cannot name any particular hormonal failure, but think there must be a "general failure of the endocrine functions." Even for such desperate cases of "Twilight of the Glands" there is hope, in a sort of *omnium gatherum* of endocrines, surely foreseen, as everything else, by the Bard.

"Fillet of a fenny snake,
Eye of newt and toe of frog,
Wool of bat and tongue of dog,

[Desiccated pituitary, adrenal cortex, desiccated brain, excised lymph gland]

Adder's fork and blindworm's sting,
Lizard's leg and howlet's wing,
Scale of dragon, tooth of wolf"

(Excised spinal cord, dried extract of testes, thyroid extract—put them all in!) This prescription, to be taken by the mouth, is found in the catalogue of a well-known firm.

The clinician may well cry "Halt," and say: "Insulin we know, thyroid we know, adrenaline and pituitrin we know, but what are these?" The time has surely arrived to ask for a clear evaluation of the usefulness and efficacy (if any) of the vast majority of endocrine productions of the present day, and, in particular, a

positive guarantee of the fundamental "replacement power" of the preparation. Do, or can, the physiologists speak with a clear and unanimous voice? It appears necessary, further, to settle the question whether clinical dogmatism and hypothesis, allied with commercial zeal, have outrun the limits of ascertained facts.

If the results of a recent transatlantic investigation are to be credited, in that any activity of most glandular preparations is due to a "hotting-up" with thyroid, we might seem to be in for a severe "debunking" of existing endocrine therapy.—I am, etc.,

London, W.1, June 16th.

C. JENNINGS MARSHALL.

Psychological Effect of Hysterectomy

SIR,—I was much interested in Dr. Winifred Coppard's letter (June 9th, p. 1048) on the psychological effects of hysterectomy. The following is a case which indicates at least the possibility of the operation being followed by no adverse effects of this nature.

The patient, a married nurse, a primipara, had a 10 lb. baby at the age of 36. Forceps were used. Afterwards she had a chronic pelvic discharge. Some three years later she had a three months' miscarriage, followed by severe menorrhagia, anaemia, backache, and chronic ill-health. The uterus was enlarged. Conservative treatment was tried without effect, and hysterectomy was advised and carried out. At operation a large uterus, with unhealthy mucous membrane, was found. One ovary was cystic and was removed, the other was left. The patient recovered quickly, and three months afterwards was not only running her house, but taking in and nursing convalescent patients. As regards intercourse, whereas before operation she had felt too ill and weary to be interested, afterwards she derived normal pleasure.

Now this patient was a member of a large family, and singularly well adjusted to life. Her whole history showed an adaptable disposition and an ability to tackle difficulties. Is not this the important factor? There are cases in plenty like Dr. Coppard's, where hysterectomy has been followed, not only by adverse psychological effects, but by definite mental breakdown; but so are there cases where the normal processes of puberty, childbirth, and the menopause have been followed by similar effects. Surely hysterectomy, like these latter, is only one of many precipitating causes which may be the last straw to a maladjusted personality. A knowledge of the psychological make-up of the patient should have its due place when deciding for or against operation.—I am, etc.,

Lincoln, June 11th.

MARION GREAVES.

Hyperpiesia

SIR,—Dr. Graham Grant asks in your issue of June 16th for opinions as to whether alcohol is a contributory cause in hyperpiesia. I imagine that no one can give a dogmatic reply to his inquiry, but it is quite certain that hyperpiesia of severe degree is frequently encountered in persons who have never touched alcohol, and that extreme hyperpiesia is not obviously more common amongst alcoholics than amongst the remainder of the community.

Of the therapeutic substances which are of value in the treatment of the condition the habiturates occupy an important position, and I am personally of opinion that their little cousin alcohol is not infrequently of some value also; in stating this I am well aware that careful judgement is necessary in order that the dose permitted may have a sedative effect, and not, by depressing the centres of control, merely encourage the patient to indiscretion.—I am, etc.,

London, W.1, June 15th.

T. IZOD BENNETT.

"One-shot" Immunization Against Diphtheria

SIR,—I have read with much interest your leading article on diphtheria immunization in the *Journal* of June 16th (p. 1081). I have also read the M.R.C. report on active immunization against diphtheria; which prompted the appearance of your leader.

I note that you emphasize the possibilities of alum preparations of toxoids as potent diphtheria prophylactics for use in this country. This statement marks a definite advance in the attitude with which these powerful prophylactics are regarded by the medical profession, especially in view of the expression of opinion which recently appeared in a leading article in a contemporary British journal, to the effect that the preparation of such prophylactics had not yet reached a stage which would warrant their use on the general child population of Great Britain. It is usual in such commentaries to refer to the work of Saunders in Cork: in a series of 579 children who were immunized by three injections of alum toxoid four subcutaneous abscesses were encountered. The leading article which is referred to above suggested that such results would not be tolerated in this country. The chief factors which have delayed a more general use of alum preparations here are three: (a) anxiety regarding the occurrence of the general and local reactions which are liable to appear in certain individuals on the injection of high-value toxoids; (b) the fear of subcutaneous "cold" abscesses at the injection sites; and (c) general apathy regarding the superiority of the newer prophylactics over the much-tried T.A.M.

Eighteen months' experience of high-value toxoids has convinced me that, either alone or with added alum, they will entirely replace the older preparations. As a continuation of my work on these toxoids, a preliminary account of which was published in the *Lancet* (1934, i, 678), I have been carrying out observations on their efficiency when combined with alum ("alum-formol-toxoid," A.L.F.T.), and papers are in preparation dealing fully with these results. Since, however, your leading article has laid special emphasis on the possibility of inducing immunity by means of one injection, it seems desirable to publish a brief note with reference to a few cases which have been dealt with from this standpoint.

So far I have carried out immunization by means of a single dose of prophylactic only on small batches of children, and seventy-five children have been dealt with. It is possible to give preliminary results in the case of fifty-nine children, each of whom received only one dose of A.L.F.T.

(a) Of seventeen children of school age eight were Schick-negative four weeks after the injection, and twelve were negative six weeks after the injection. The percentages negative at four and six weeks were therefore 47.0 ± 8.2 and 70.6 ± 7.5 respectively.

(b) Of twenty-two children in another batch, nine were negative four weeks after the injection. This gives a percentage negative of 40.9 ± 7.1 .

(c) Of twenty boys aged 15 to 18 years who resided in an institution seventeen were negative four weeks after the injection. In this case the percentage negative is 85.0 ± 5.4 .

Although this preliminary series is small, the probable errors show that the results are statistically significant. Expressed in another way, we may say that in any series of children of school age in this locality, each of whom receives one dose of A.L.F.T., the expectation is that in four weeks about 40 to 50 per cent. will be negative, and by the sixth week this percentage will have increased to about 70. In older children we might expect about 85 per cent. to be negative in four weeks. (These results refer only to individuals who were found to have a definitely positive Schick test before the injection was given.)

So far as reactions are concerned, my experience is based not only on these seventy-five children, each of whom received only one injection, but also on a further series of 227 persons,

each of whom received two or more injections. This makes 302 individuals in all. In each case preliminary Schick and Moloney tests were performed. Reactions of the toxoid type were encountered only in those cases in which this test strongly suggested that such reactions might follow the injection. None of these reactions was severe. More important perhaps is the fact that in no case has anything in the nature of subcutaneous abscess formation, as was found by Saunders with alum toxoid, been met with.

It should be remembered in assessing any results of single injections that a Schick test performed six weeks after the injection is equivalent, so far as the total time is concerned, to a similar test performed four weeks after the second injection where there is an interval of two weeks between the injections. These results strongly suggest that the efficiency of alum preparations is not merely an ideal of the future but is about to become an established fact.

In conclusion, may I point out that it is essential not to alienate the public. With these powerful prophylactics it is extremely desirable to avoid severe reactions. Although in some cases the Moloney test may be dispensed with when moderately powerful toxoids are used, the time is not yet ripe for immunization with alum preparations without its preliminary use. All the materials used in these investigations (both F.T. and A.L.F.T.) have been supplied through the courtesy of Dr. R. A. O'Brien of the Wellcome Research Laboratories.—I am, etc.,

Public Health Department, E. ASHWORTH UNDERWOOD.
Leeds, June 16th.

Diphtheria Immunization

SIR,—In your very kind reference to our report on active immunization in your leader of June 16th it is stated that we argue "artificial immunization may increase the 'virulent carrier rate' and the occurrence of diphtheria among the inoculated." I assume "inoculated" is a slip of the pen for "uninoculated." Because the whole thesis was that artificial immunization increases the virulent carrier rate in the protected children, which in turn increases the case rate among the unprotected members of the same community. I feel that attention should be drawn to this error, as the sentence, isolated from the context, would, as it stands, make a splendid piece of anti-vaccination propaganda.—I am, etc.,

R.N. Hospital, Chatham, June 16th. SHELDON F. DUDLEY.

* Surgeon Captain Dudley is right. Owing to a typographical error inoculated was printed instead of uninoculated.—Ed. B.M.J.

SIR,—In your leading article on diphtheria immunization you mention a scheme in "West Kensington." This scheme is not operative in West Kensington alone, but covers the whole of the Royal Borough of Kensington. The scheme was drawn up by the Kensington Division of the British Medical Association and the Council of the Royal Borough of Kensington.—I am, etc.,

J. COHEN,
London, W.2, June 16th. Honorary Secretary, Kensington Division.

Intracranial Injury in the Newborn

SIR,—Dr. Alan Moncrieff's valuable paper in the *Journal* of June 16th (p. 1068) will be welcomed by all who are concerned with the care of the newborn baby. The treatment suggested seems reasonable and is well worthy of thorough trial. But even if the results obtained with further experience do not support Dr. Moncrieff's optimism I would consider his paper important because it stresses a fundamental fact—namely, that the type of

intracranial trauma suffered by many infants should be described as cerebral congestion, oedema, and contusion rather than intracranial haemorrhage. I emphasized this point in 1922,¹ and it was again brought out by J. N. Cruickshank in the report on his extensive pathological investigations. My clinical experience in the Liverpool Maternity Hospital during the past fourteen years supports the view that the intracranial condition in many damaged infants is one which, while full of danger to life during forty-eight to seventy-two hours after birth, may resolve after this period has been successfully passed, and leave no permanent physical or mental disability.

We have got beyond the stage of believing that the death of a damaged infant is always a merciful release, and we are fully justified in employing every line of treatment likely to help the baby to survive the early period of danger, even though we may not be able to make an exact differential diagnosis between intracranial haemorrhage on the one hand, and cerebral congestion, oedema, and contusion on the other. I hope that Dr. Moncrieff's suggestion will receive trial in many places, and that the results will be reported.—I am, etc.,

Liverpool, June 18th.

NORMAN B. CAPON.

Criticism of Ante-Natal Work

SIR,—Mr. A. J. Wrigley's recent article on ante-natal care (*Journal*, May 19th, p. 891) is a timely reminder that its end-results, as judged by maternity statistics, demand a kind of stock-taking review. The system of preventive medicine which we call ante-natal care has now been in operation long enough to enable us to form an opinion of its value in preventing deaths and disability due to childbearing, and it is therefore right that we should stop to consider whether a method which must be inherently sound has or has not produced the results originally expected. Mr. Wrigley's article of criticism suggests that there has been a partial failure in the practical application of the method, and subsequent correspondence has shown that considerable interest has been aroused. It is fortunate that the Section of Obstetrics and Gynaecology at the forthcoming meeting of the British Medical Association is providing a session for the debate of so important a matter.

There is no doubt that the results, as set forth by Mr. Wrigley, must set us thinking hard. It is inevitable that those of us who are engaged in the teaching and practice of obstetrics regard ante-natal care as a vitally important part of our work, because it is obvious that the detection of abnormal conditions and their treatment, where possible, should necessarily lead to improvement in the end-results. And therefore, after so much energy and enthusiasm spent in teaching and writing, we must confess to something of surprise and disappointment when confronted with the figures of Mr. Wrigley's paper. Discussion of the details of diagnosis and treatment are, of course, inevitable, but before descending to this it would be well to consider whether the general teaching of students, the attitude of mind towards certain of the supposed abnormalities of pregnancy, the public administration of the system, and its partial adoption by individual practitioners, are each or all responsible for the failure to obtain the results we hoped for.

As the original enthusiasts and present teachers of the young student and post-graduates the obstetricians must necessarily bear the chief criticism. The other participants may rightly point to us and say that they are only doing what we have taught. We must examine ourselves, and ask ourselves whether, for example, it is really proper to regard the "high head" as a common indication of contracted pelvis and therefore of induction of labour or

Caesarean section. Public authorities might reconsider the capacity of a whole- or part-time ante-natal officer, who sees little or nothing of actual labour, to offer opinions on the prognosis of labour in a given case of doubt. All of us may ask ourselves if we have not elaborated a pseudo-pathology of pregnancy by our emphasis of details which have no real significance, so that our attitude of mind is biased in favour of an actually unnecessary interference. And, finally, is ante-natal care applied to the vast majority of pregnant women by individual practitioners who accept the responsibility of conducting labour? There is evidence published in recent departmental reports that many women have no supervision, and many more only a perfunctory attendance, which is of no real value whatever.

I feel that in this discussion it is useless to descend to recriminations, for all of us who practise and administer the ante-natal system are open to criticism for the partial failure that is now admitted by all who are not handicapped by an oblique vision of the problem. I am hoping that the Bournemouth meeting will yield criticism which is constructive, and will pave the way to a second phase of ante-natal care which will be based upon a better understanding of the pathology of pregnancy.—I am, etc.,

London, W.1, June 18th.

ALECK BOURNE.

Prevention of Puerperal Sepsis

SIR,—As a general practitioner I was much interested in Dr. W. H. F. Oxley's paper on "Prevention of Puerperal Sepsis" (*June 9th*, p. 1017), and agree with it all. I have two suggestions to make with regard to it. He is very keen on everything being left to nature as far as possible, there being very little vaginal examination. I have made inquiries at several hospitals, and find that students are always told to guide the forceps with the other hand in the vagina. This means an unnecessary insertion of a hand in the vagina. When it is known that the head is presenting, and that the os is dilated, it requires no force whatever to put on the forceps. They drop into place if handled properly. If they do not the operator is not skilled enough to be practising midwifery.

Dr. Oxley records twenty cases of pyrexia after abnormal confinements. In seven of them the hand was introduced into the uterus during or after the third stage of labour, in most cases due to a long-retained placenta or to unnecessary continual massage of the uterus. I have looked at all the books on midwifery which were found for me in the library of the B.M.A. I wanted to find out the treatment of the umbilical cord, and in all but one it was stated that it had to be tied in two places and cut in between. In *A Short Practice of Midwifery* (Jellet) it is stated:

"It has often been suggested that the omission of the ligature on the placental side of the cord, by allowing the blood of the placenta to escape, facilitates the mechanism of the third stage of labour. If this is really so, such omission is advisable. If it is not, I prefer a second ligature."

Of course, it must not be done if there is a twin to follow.

For years I have not tied the placental side, but I do not know from whom I learned it. If those who wrote the book referred to had troubled to think about it they would have advised leaving the placental side unligatured. I must own it requires some imagination to reckon what happens in the placenta when the blood runs out of it. It certainly makes it smaller, and so the uterus has less to turn out. Also, I think, it must separate more easily from the uterus. None of the other mammalia in nature tie their umbilical cords! If it were always left free I believe we would have fewer cases of puerperal sepsis.—I am, etc.,

London, W.10, June 14th.

NORMAN H. JOY.

¹ *Journ. Obstet. and Gynaecol. British Empire*, 1922, xxix, 572.

SIR,—After reading countless articles on the prevention of puerperal sepsis in general practice, it is interesting and refreshing to read Dr. W. H. F. Oxley's lecture in your issue of June 9th. It is eminently helpful to the general practitioner. He describes a technique, uncomplicated and easily carried out, instead of the masked, gloved, and gowned spectre which the bacteriologist would have us present to the already nervous young girl about to go through the trials of her first labour. He draws attention to the part played by the forceps in the causation of puerperal sepsis. This state of affairs is bound to continue so long as the forceps is regarded by many as a blessed instrument for the saving of time, and enabling the doctor to keep his appointments, social and otherwise.

The question of retained placenta is mentioned, the current treatment of which results so often in sepsis. The method described by Majon in 1826, by Jarcho in 1928, and later by Mr. Currie of Leeds in 1933, seems worthy of more general adoption. This consists in the injection of the umbilical vein with sterile saline under pressure. In Mr. Currie's series of fifty cases he showed that the method was simple, free from danger, and highly successful. It would be interesting to learn the results of this treatment in a large series of cases in hospital and general practice.—I am, etc.,

R. D. B. WRIGHT, M.B., Ch.B.

Hornsea, East Yorks, June 15th.

Injuries of the Knee-joint

SIR,—I was surprised to read Dr. Stewart's criticism, in the *Journal* of May 5th (p. 824), of Mr. T. P. McMurray's masterly exposition of this subject (April 21st, p. 709). It seems strange that a belief should still exist that injury to the semilunar cartilages ever occurs in other than the flexed position of the joint. I have always thought that this bogey had been finally slain in a paper read in (I think) 1911 by my old chief, the late Mr. A. M. Martin of Newcastle-on-Tyne, than whom few, if any, had greater experience of these injuries. There is nothing in Dr. Stewart's description of his cases to prove that the injury occurred in extension: the presence of locking in extension—he does not say full extension—is the best proof of its having occurred in flexion. In the absence of lateral mobility in a fully extended joint, injury to a cartilage is produced by the continuance of a force which has already caused severe damage to other structures.

I have radiographs of a complete external dislocation of the knee-joint, where the patient regained full function under the conservative treatment so ably advocated by Mr. McMurray. The dislocation I reduced with surprising ease. Both crucial and internal lateral ligaments were completely torn through. Mr. Martin examined the case with a view to suture of the ligaments, and decided against intervention. The limb was put up in poroplastic just short of extension, with the excellent result already mentioned.—I am, etc.,

G. STEWART WOODMAN, F.R.C.S.ED.

Chief Surgical Specialist to the
Government of Iraq.

Baghdad, June 7th.

Prescription of Thyroid

SIR,—I would not venture to trespass on your space if I were not convinced of the inaccuracy of part of the statement on page 1039 of your issue of June 9th with the implication of ignorance on the part of practitioners of medicine in prescribing this substance (tab. thyroideum B. P.): "Several firms, especially in the North of England, are now manufacturing twenty times as many . . . 5-grain tablets . . . as they did before." This is certainly not true in our own case, and the predominant

use of the lower range of dose is indicated by the fact that during the past year the total number of tablets made in the smaller doses—grains $\frac{1}{2}$, 1, $1\frac{1}{2}$, 2, and 3—outnumbered the 5-grain size by 27 to 1, and the strengths for the most part commonly asked for were the $\frac{1}{2}$, 1, and 2 grain.

Further, for a very great many years it has been the practice of this firm to recommend to medical men the desirability of ordering thyroid in terms of dried tissue. In 1923 I read a paper before a branch of the Pharmaceutical Society on "Ductless Glands and their Relation to Practical Medicine," in which I again drew attention to this point in the following words: "I should like to emphasize once more the fact that it would be an immense advantage if prescribers would forget altogether the relationship between fresh gland and dried gland and free their prescriptions from all ambiguity by stating their doses clearly in terms of thyroideum siccum."

The figures given above would seem to show that medical men drawing their supplies from us do not feel the difficulty set forth in your note, and we believe that if, in the South, the statement of dosage had been long ago confined to terms of the dried gland no such confusion in prescribing, as is said to exist, could possibly have arisen.—I am, etc.,

WILLIAM MARTIN, M.A., M.D.

Director, Brady and Martin, Ltd.

Newcastle-on-Tyne, June 12th.

SIR,—With reference to your article on the prescription of thyroid in the *British Medical Journal* of June 9th, it is a matter of great importance that this question of the relationship between dry thyroid and fresh thyroid gland should be made absolutely clear, because there is no doubt, as you say, that 5-grain tablets of dry thyroid are being frequently prescribed when fresh thyroid gland is intended. At the same time, there is one point in your article which is not quite correct. You state that the B.P. dry thyroid is five times as strong as the fresh gland preparation. The B.P. preparation is standardized to contain 0.1 per cent. of iodine in combination as thyroxine. The relationship to the fresh gland therefore depends entirely on the original iodine content of the gland from which the B.P. preparation is made, and may vary within quite wide limits. Usually one part of the B.P. dry thyroid is equivalent to much less than five parts of fresh gland, the average being probably about three parts. This makes a dose of 5 grains of B.P. dry thyroid equivalent to about 15 grains of the fresh gland.—I am, etc.,

Allen and Hanburys Ltd., Bethnal
Green, E.2, June 18th.

NORMAN EVERS,
B.Sc., F.I.C.

Diverticulitis.

SIR,—I cannot agree with your correspondent Mr. J. L. Joyce (*Journal*, June 16th) that a temporary caecostomy is an adequate operation in cases of acute diverticulitis, where there is a threat of such complications as obstruction, perforation, or colo-vesical fistula. While caecostomy may enable the patient to get over the immediate crisis, the latter is almost certain to recur very shortly. If the object of the caecostomy is to enable the contents of the colon to be kept liquid, an appendicostomy is a more suitable procedure, but these complications of acute diverticulitis are very serious conditions, and a transverse colostomy, which completely prevents the faecal contents of the colon from reaching the damaged area, is, in my opinion, the only procedure which is likely to prevent such complications. A section of colon which has been so seriously damaged by acute diverticulitis that it is giving evidence of causing obstruction, or of being about

to perforate, is most unlikely to recover sufficiently in three weeks to resume its normal function.

In a great many cases, unless some form of operation to deal directly with the damaged bowel can be carried out, the colostomy will have to be permanent. After all, there is no form of medical treatment that can improve the anatomical abnormality produced by the diverticula, nor can diverticula, once formed, be made to disappear. All that medical treatment can do is to so alter the local conditions that the inflammatory manifestations have a chance of subsiding. The ideal treatment is a temporary transverse colostomy, followed, when all the inflammation has subsided, by a resection of the affected portion of bowel. Unfortunately, it is not very often that this is possible, and in many cases the patient has to be satisfied with a permanent colostomy, which, after all, is not too severe a price to pay for prolongation of life and absence of pain.—I am, etc.,

London, W.I., June 15th. J. P. LOCKHART-MUMMERY.

Ephedrine in Asthma

SIR,—The omission of a hyphen in the last word of my letter (June 16th, p. 1097) conveys a meaning which is the antithesis of that intended. The sentence should read: "In conclusion, I should like to mention that the best sympathetic stimulant is cold, which can generally be obtained by good ventilation and under-clothing."

The matter is of considerable importance, as I am certain that over-clothing is an important aetiological factor in the causation of asthma, particularly in children. This is very well seen in measles convalescents. Bronchitis in these cases generally occurs when the heat-regulating mechanism is unduly stressed by excessive clothing or an overheated sickroom. If one garment only is permitted, and the room temperature kept about 60° F., bronchitis is an extremely rare complication.

Reduction in clothing is necessary when thyroid-ephedrine treatment is used, as these drugs in combination appear to cause an increase in the metabolic rate, and I have known pyrexia to occur when heat loss has been restricted.—I am, etc.,

Bradford, June 16th.

H. S. RUSSELL, M.D.

* * We cannot find any authority, in the *Oxford English Dictionary* or elsewhere, for the use of a hyphen to distinguish between "underclothing" (the act of wearing few or insufficient garments) and "underclothing" (garments worn below the upper or outer clothing); or for a corresponding distinction between the two senses of "overclothing." But we willingly insert the two hyphens in order to emphasize Dr. Russell's point. Incidentally we might remark that during last week-end all underclothing was overclothing.—ED., B.M.J.

Ethyl Chloride Analgesia in Minor Surgery

SIR,—The question of time is an important one to the practitioner, and a simple, safe, rapid, and efficient analgesic would supply a long-felt want. For example, the cleansing of a wound, removal of a nail, extraction of a tooth, incision of a simple abscess or whitlow, or extraction of a splinter is often too petty to warrant the risk of a general anaesthetic, the bother of gas, or the time necessary to produce local anaesthesia. In consequence, the patient is often expected to put up with the pain.

A series of over two hundred cases has encouraged me to report on the practical utility of ethyl chloride analgesia. The dangers of ethyl chloride are well known. It is not my intention to deny or minimize those dangers, but to point out the enormous difference between the use of ethyl chloride as an anaesthetic and as an analgesic.

It may not be well known that all general anaesthetics produce an analgesic effect preliminary to and distinct from actual anaesthesia and relaxation. The former effect can be isolated from the latter and made use of, and is best obtained with a pleasant and non-irritating substance such as ethyl chloride. The method of administration is as follows:

Spray or drip ethyl chloride on a thin (eight-inch) sheet of cotton-wool, about four inches square, held on the palm of the hand. The area sprayed should be large enough to cover the nostrils and open mouth of the patient. Cease spraying when the moisture trickles through to the palm—this requires five to seven cubic centimetres. Place the moistened wool over the open mouth and nose of the patient, who may be sitting or recumbent. Tell him to blow ten or twelve times forcibly through the mouth fairly rapidly, explaining that at the end of that time he will be in a state to appreciate pressure but not pain. At the tenth breath do what is necessary as quickly as possible. The analgesia will last ten to thirty seconds, which is usually ample if everything has been got ready beforehand. If the operation is calculated to take about ten seconds only the cotton-wool should be removed at the tenth breath, otherwise it may be left on the face without danger, during the performance of the operation. As consciousness is retained the patient will, for example, open his mouth on being so requested, and will keep quite still while one or more teeth are being extracted.

This method of analgesia was introduced to me by Dr. Peake, a South African dentist, who has extracted several thousands of teeth by its aid. I have his assurance that he has never seen any ill effects from its use. My own more limited experience has been similar. The ethyl chloride is breathed through a thin layer of cotton-wool, and the administration is therefore as "open" as it could possibly be. Consciousness is always retained in some measure—it is impossible to anaesthetize anyone in fifteen or sixteen seconds. The subjective sensations vary. I have administered the analgesia to myself for a dental extraction, and suffered no pain whatsoever, experiencing dizziness and fullness in the head, and pressure on the jaw. In four or five seconds the patient is himself again—there are no after-effects, such as headache, nausea, or vomiting. In this respect I have found it not unsatisfactory to administer analgesia on a full stomach. I have repeated the analgesia on one occasion after a few minutes' pause with no ill effect, but doubt the advisability.—I am, etc.,

General Hospital, Northampton, M. AMOLS, M.B., B.Ch.
May 30th.

The Medical Charities

SIR,—As honorary secretary of the Royal Medical Benevolent Fund I feel that a reply to Dr. Arnold Gregory's letter in your issue of May 26th on this subject is desirable. All those who work for medical charities will be in sympathy with any attempt to improve the position, and I sympathize with his desire that the facts should be faced clearly and boldly, but his letter contains suggestions which might mislead some and possibly may have the effect of alienating sympathy among those who might deduce from his letter that the medical charities are unsatisfactorily administered.

If much ignorance still exists regarding the charities the fault cannot be laid at the door of the various organizations concerned: for no Press could have given greater or more constant publicity to the charities than the medical press has done for many years. The widespread organizations working under the Charities Committee of the B.M.A., under the administration of this Fund and of Epsom College by honorary local secretaries, have done all that is possible to bring our needs before the whole medical profession, and if the response is inadequate it is due to the apathy of the profession.

Dr. Gregory's suggestion for the formation of a capital fund of £25,000 surely implies that he is not cognizant of the magnitude of the work already being carried out. It will suffice to state that the invested capital of this Fund alone is £160,267, that the annual income derived from subscriptions is £11,856, and that the total amount distributed to beneficiaries in 1933 was £18,900.

In agreement with Dr. Henry Robinson, I urge concentration upon increasing annual subscriptions and legacies rather than any special form of intensive short-lived campaign. Success depends upon the good will of the profession and in the belief and knowledge that the charities are doing really useful work. We seek the interest of men and women who are willing to act as honorary local secretaries, as it is chiefly by personal persuasion that the subscription list can be improved.

I must reply to one criticism which appears in Dr. Gregory's letter—that the grants are pitifully meagre, since it is frequently used by others, often as an excuse for refusing to subscribe, on the grounds that a grant of £26 is so inadequate that such a fund is not worthy of support. While it is true that the Fund limits its grants to £40 per annum to a medical practitioner and £26 per annum to dependants, it is quite fallacious to suggest that our help ends there. Applicants in great poverty are advised and assisted in their applications to other medical charities and to non-medical charities. Our Ladies' Guild, an auxiliary of the Fund, assists not only with grants, but with food, coal, and clothing and with education, as these few examples show.

Widow, aged 66, is in receipt of Fund grant, £26; Guild, £12; Epsom Pension, £40. Total from medical charities, £78, in addition to outside charity, £10, and very small personal income.

Widow, aged 53, with three children, earning what she can by letting rooms; is assisted by medical charities, Fund and Guild, to the extent of £66 per annum.

Daughter, aged 60, with a private income of £12; is in receipt of medical charity, Fund and Guild, £65.

Widow, aged 67; some help from relations; medical charity, Fund and Epsom College, £66 per annum.

Widow, aged 74, in receipt of old age pension; medical charities, Fund and Epsom College, £71 per annum.

It should be appreciated that no applicant in great poverty is ever left to fend for herself on £26 per annum, for this grant does not reveal the full extent of the assistance which the Fund arranges; and, further, no deserving applicant has ever been refused help by the Fund, although in a few isolated cases applications of no great urgency may have been postponed to a future meeting.

It is frequently said that the percentage of medical practitioners who subscribe to medical charities is distressingly small, but it is overlooked that a very large number subscribe indirectly through a levy by their area Panel Committees; and that, in addition to the well-known central charitable organizations, some counties and districts have a medical charity of their own, the existence of which is little known to the profession in general.

If all these organizations are considered together the medical profession will be found to suffer nothing by comparison with the charitable records of other comparable professions in this country.

The need is undoubtedly great and is likely to increase. The immediate need for which I appeal is an increase in the number of annual subscribers, and I appeal to every subscriber to make a special effort this year to enrol at least one new subscriber, and further I appeal for offers of volunteers to act as honorary local secretaries.

The ultimate object for which we are all working is the achievement of such a financial position as would enable us to meet all our applications in that generous manner which we all desire. That object will, however, require in the future, amongst other things, a much

closer co-ordination between all medical charities, both collecting and distributing. These problems are outside the scope of this letter, which is intended to eradicate a possible wrong impression which Dr. Gregory's letter may have left.

The Committee of Management of the Royal Medical Benevolent Fund is only too aware that there is room for great expansion, but that depends entirely on money, but, with the present resources at their disposal, I submit that the work of the medical charities, of whose working I have intimate inside knowledge, is carried out not only efficiently but with that courtesy and kindness one is accustomed to associate with our profession.—I am, etc.,

R. M. HANDFIELD-JONES,

Honorary Secretary, Royal Medical Benevolent Fund.
11, Chandos Street, Cavendish Square, W.1, June 12th.

SIR,—The financial position of the medical charities has always been a disgrace to the profession. I am surprised that so little notice has been taken of Dr. Gregory's letter (May 26th, p. 962), and take it as evidence that the consciences of the individual members of the profession have not yet been awakened to the fact that it is the duty of every member to help his fellow members and their needy dependants in old age and infirmity. I do not approve of some of the methods of raising money, such as whist drives, lotteries, etc. From my limited experience of collecting I am sure that the personal canvass is the best method. I understand that commercial travellers have a box on the table at every ordinary dinner, and that a large amount is collected in this way. I would suggest that at every medical meeting there should be a box on the table for donations to the Charities Committee of the British Medical Association.

I had the curiosity to read the report of the Royal Medical Benevolent Fund, which has just been published, and count the number of subscribers from this town. There are about thirty-six, and they subscribed under forty guineas. In addition, the Panel Committee gave a donation of twenty-five guineas and the Association collected twenty-five guineas and tenpence.

I suppose there are about five hundred practitioners in Birmingham. There are over 450 panel practitioners, who receive over £180,000 between them. In addition, there are non-panel practitioners, physicians and surgeons, and specialists. Between them all under a hundred pounds was subscribed last year to the Royal Medical Benevolent Fund. Surely there is room here for a personal canvass.—I am, etc.,

Birmingham, June 17th. ROBERT ANDERSON, M.D.

The Services

HONORARY SURGEON TO THE KING

In the *London Gazette* of June 15th the War Office announces that Major-General H. R. Nutt, M.D., F.R.C.S., Indian Medical Service, V.H.S., is appointed Honorary Surgeon to the King, February 28th, 1934, vice Major-General J. D. Graham, C.B., C.I.E.; M.B., Indian Medical Service (ret.).

SHORT-SERVICE COMMISSIONS IN THE R.A.M.C.

The following candidates who presented themselves in June, 1934, for short-service commissions have been granted commissions as lieutenants on probation in the Royal Army Medical Corps:

W. M. E. Anderson, M.B., B.Ch., H. B. Wright, M.B., B.Ch., J. Boyle, L.R.C.P., L.R.C.S., R. H. Foster, B.Ch.Camb., J. S. Ruddell, M.B., B.Ch., A. G. D. Whyte, M.B., B.Ch., A. L. Pennefather, M.B., B.Ch., C. G. O'Driscoll, M.B., B.Ch., D. T. Swift, M.B., Ch.B., F. E. Buckland, M.R.C.S., L.R.C.P., A. MacLennan, M.B., Ch.B., J. H. J. Crosse, L.R.C.P., M.R.C.S., J. Morgan, M.B., Ch.B., R. A. Stephen, M.D., E. H. P. Lassen, M.R.C.S., L.R.C.P., R. S. Vine, L.R.C.P., M.R.C.S., I. Buchanan, M.B., Ch.B., J. E. Jameson, M.R.C.S., L.R.C.P., N. W. Allen, M.R.C.S., L.R.C.P.

Medico-Legal

BUSINESS RELATIONS BETWEEN DOCTORS*

PARTNERSHIPS

If partners are well matched and work together, their combined strength is a great deal more than the sum of their individual resources. If partners are ill matched, they had far better separate. Many partnerships are wrecked by jealousy, but perhaps more of them founder because the partners never were at any time temperamentally fitted to work together. The bed-rock of a partnership is mutual good will, and intending partners should consider most seriously and at some length whether they will probably get on well enough with each other to work together for many years. If they have any doubt they should not start. Possible causes of disagreement should be frankly faced, discussed, and guarded against. Experience shows that most of the difficulties of working in partnership can be overcome if partners behave in the right way from the start. The best advice that can be given to an intending partner is to consult the secretary of his defence society or of the B.M.A. These officers are experts in medical business relationships, and can also recommend solicitors and accountants in whom the doctor can place every confidence.

A fruitful source of later discord is the discovery by the new partner that his share is not worth what he thought it was. His disappointment is very likely to lead him to express doubts of his partner's good faith, and a breach thus caused may easily widen into a rupture. The purchase of a share is governed by the same considerations as the purchase of a whole practice, which will be dealt with fully in a later section. The chief safeguards are thorough investigation of the accounts by an accountant who is expert in medical work, and careful local inquiry by an experienced medical agent.

When the intending partners have decided that they can exclude every likely cause of disagreement, they should approach a firm of solicitors with experience in medical work and have the agreement properly drawn up. They should not attempt to work together until this has been done. Sometimes partners let years go by before drafting, let alone signing, the agreement. If any disagreement arises the position is very complicated and disastrous litigation may develop.

The following experience¹ shows how badly a medical man may fare through beginning to work in partnership before the legal agreement is drawn up and signed.

There were two partners, A and B. B retired and X, another practitioner, agreed to buy, subject to certain conditions to which A agreed. No mention was made of any preliminary assistantship, and X understood that A had accepted him as a partner. B was about to undergo an operation, and was to arrange his affairs before he left the town, so X paid up the bulk of the purchase money and signed an agreement to take over B's house. X started work with A as a partner and worked for five weeks. He was introduced to A's patients as A's partner. He went on to the panel and his name was substituted for B's on the cards. A and X opened a common banking account, and steps were taken for X to take over B's share of the lease of a common surgery. After discussion with A, X caused to be printed 2,000 copies of a new joint account form, and A bought and paid for X's plate with both names on. X called on all the doctors in the town as A's new partner.

After five weeks, with A's consent, X went to London to make arrangements for moving his furniture in, and paid a locum tenent during his absence. On arrival in London he received a letter from A saying that he thought it would be a mistake to proceed further with the partnership, and that B had acted hurriedly. At the same time X learned that B was dangerously ill after the operation. X recovered his purchase money from B, but had to look elsewhere for a practice. He had to tell all his friends that the arrangement with A had fallen through; he had received a number of introductions to people in A's town, and he felt that he had suffered considerable moral damage, apart from out-of-pocket expenses and loss.

* The first of these articles, by a legal correspondent, appeared in the *British Medical Journal* of June 9th, 1934 (p. 1033).
¹ *Lancet*, 1926, ii, 150.

It is not at all improbable, however, that a court of equity would consider that A, by his conduct, had induced X to regard himself as A's partner, and that he would be liable for any damage to X caused by his subsequent withdrawal.

THE PARTNERSHIP AGREEMENT

Although the drafting of the partnership articles should be entrusted to a solicitor with special experience in medical work, it is desirable that intending partners should have a good idea of what the articles should contain. Many of the conditions of a properly drafted agreement are, at first sight, unnecessary and even unintelligible; to appreciate them the doctor must know their history and the results of omitting them in the past. Barnard and Stocker's specimen form of articles, with notes, are the best if not the only published source of this information. Briefly,² the agreement should define: the duration; the terms on which the in-coming partner shall acquire and increase his share; the mutual rights and duties of the partnership (the division of labour); the partnership property and expenses; the fees to be charged; the terms of dissolution and the restrictive covenants by which an outgoing partner shall bind himself not to compete with the remaining partners; and the mechanism for settling disputes. Provision should be made for the keeping of accounts, the division of profits, holidays, and the absence or incapacity of a partner.

Partnerships nearly always originate in the purchase by a junior of a share in the practice of a senior practitioner. The premium is usually paid in a lump sum, before the partners start to work together. There are good reasons for this custom. If the junior agrees to pay instalments and fails to pay them regularly, the senior will naturally be discontented and friction will arise. If he does pay them regularly, he may have so little money left that he cannot keep up a proper appearance or meet his tradesmen's bills, and the credit of the practice will suffer. As he gets no share of the money owing by patients at the time the partnership begins, he will not receive his full share of the profits for a considerable time. The same objection applies to admitting a partner who has borrowed money to pay his premium, unless he has borrowed it from a recognized society under its scheme for assisting young practitioners to start in practice.

DURATION OF PARTNERSHIP

In fixing the duration of the partnership the partners have to remember that the fundamental object of all their business arrangements with each other must be to preserve the goodwill and connexion of the practice, so that when the partnership is dissolved by death or some other cause, each partner shall be able to realize the proper value of his share. The risk of partners quarrelling and being unable to carry on together is always present, and it is essential that if this happens any partner shall be able to withdraw with as little damage to the practice as possible. One method is to give either partner the option of dissolving at certain fixed dates, such as the seventh, fourteenth, and twenty-first years, and to allow both to continue to practise in the district. The disadvantage of this method is that it holds out an obvious inducement to each partner to compete with the other to get as many of the patients as possible into his own hands, in order that when the next date comes round he shall find it worth his while to dissolve. Moreover, as each partner will be faced with a competitor on dissolution, his interest will not be worth nearly its proper value.

The agreement recommended by Barnard and Stocker is therefore that the partnership should continue for the joint lives of the partners, but that either shall be free to sell his interest at any time after the first few years, on giving six months' notice, the other binding himself to purchase it. Exactly how many years shall be allowed before either is free to sell will depend on the nature of the practice. The object is to give the junior a good chance of establishing himself. The outgoing partner covenants to give every possible assistance in the way of introducing his ex-partner to his patients and obtaining for him the appointments which he is relinquishing.

² *The Conduct of Medical Practice*, p. 50.

For details of this form of agreement readers are recommended to consult these authors' valuable textbook. Some authorities suggest that the remaining partner shall have the option of refusing to purchase, but this arrangement gives him such a stranglehold over the practice that a junior will be well advised not to consent to it. The position has, in practice, caused endless trouble.

MONEY MATTERS

The newcomer often agrees to pay a sum fixed by a competent valuer for his share of the surgery furniture, drugs, and appliances. This clause is another fruitful source of trouble, because the newcomer is apt to assume, not unnaturally, that the surgery furniture includes everything he saw in the surgery when he was first shown over it, while the senior may consider that many of the most desirable pictures, chairs, and rugs are his own property and remove them before valuation. The partners should agree on a schedule of furniture for the use of the valuer. Each partner usually provides his own motor car, but if the junior is only purchasing a small share the expense might be too much for him, and it would be better for him to contribute a fixed amount to the upkeep of the senior's cars in return for their use. It is usual for each to have his own surgical instruments.

The agreement will provide that the working expenses of the partnership, such as rent, repairs, supplies, and service, shall be paid out of the receipts, possibly from a joint banking account. The shares of the partners are defined, and each agrees to employ himself diligently in the practice and to do no other work, except, perhaps, look after a resident patient, and to accept or resign no appointment without the consent of the other partner. Although it may, at first sight, seem fair that if the senior is already a medical officer of health or a coroner he should keep the salary for himself, yet he is doing the work in partnership time, during which his junior partner is working to make profits for both.

If the junior partner comes in with a smaller share than half, he will probably want to reserve the right of buying up to one-half as soon as possible. The senior will usually want to put off the increase as long as he can, and can justly argue that the junior will not be earning half the profits for a considerable time. Barnard and Stocker suggest that the junior should be given the option of increasing his share to one-half at any time after the number of years demanded by the senior, and sooner if, at the end of any year, the accounts show that he has earned in it as much as the senior. The purchase price should be based on the original valuation and not upon the receipts immediately before the purchase, for any increase in the receipts may well be due to the exertions of the junior as much as of the senior. Each partner usually agrees to provide a competent substitute if he absents himself or is incapacitated from doing his work.

DISSOLVING THE PARTNERSHIP

Power should be given to either partner to dissolve if the other is incapacitated for a stated time, or becomes lunatic, or breaks the agreement, or damages the interests of the partnership by misconduct, or is removed from the *Medical Register*. If a partner dissolves on any of these grounds, or the partnership is terminated by a partner allowing his share to be charged with debt or being bankrupt, the defaulting partner should be considered, for the purposes of the agreement, to have died on the date of dissolution. If the partnership is ended by misconduct or breach of agreement, the other partner is generally released from any obligation to buy the offender's share, but it is better to make some sort of positive arrangement as well. The ordinary form of articles does not provide for the senior partner losing patience with the partnership, throwing over the agreement altogether, reverting as much as possible to the state of things which existed before the junior man came, and defying him to do what he likes. Such things have been known to happen. The junior can then either dissolve the partnership, in which case the senior becomes a competitor and the junior's interest in the practice is almost worthless; or he can buy the senior out, which means that he will have to pay a large sum

(which he may not be able to raise) for a practice to which he has not been properly introduced. Neither remedy is at all attractive. One possible safeguard is to frame the covenant in restraint of future practice (about which more will be said in a later article, and the object of which is to prevent a partner from selling his share and then continuing to practise next door) so that if the partnership is ended by misconduct or breach of agreement the offender shall not be able to remain in competition with his former partner. A better precaution, and one advised by the solicitors to a large defence society, is to provide that the aggrieved partner may buy the share of the offender for half the sum which he would have had to pay if his partner had died.

The agreement should lay down the price at which the survivor shall or may buy the share of a partner who dies, at various stated times after the beginning of the partnership. The authors advise that the survivor should be bound to buy. He should have easy terms of payment, but the representatives of the deceased must have adequate security, and if he can neither pay nor give good security, he must take another partner who will provide the necessary capital. If he is given the option of buying or not, he is in a position to cause the representatives of his late partner considerable trouble by obstructing the sale of their interest without actually refusing a new partner. The agreement should also provide for the taking of the final general account, and contain a clause restricting an outgoing partner from practising within a stated number of miles from the place of the partnership. It may end with a provision that any dispute shall be referred for decision to an arbitrator.

Obituary

HENRY WATSON SMITH, O.B.E., M.D.

Medical Director, Lebanon Hospital for Mental Diseases

By the sudden death in England, on June 12th, of Dr. H. Watson Smith the Near East has lost one of its very few mental specialists and the Lebanese Republic an outstanding personality. In his twenty-five years as medical director he had built up the Lebanon Hospital for Mental Diseases at Asfuriyeh, near Beirut, and at the recent annual meeting of subscribers in London the Syrian head master of a large school near Jerusalem expressed the opinion that this voluntary international hospital was one of the two institutions in Syria and Palestine which stood head and shoulders above all others. So great has been its prestige under Dr. Watson Smith's direction that sufferers from mental diseases travel from Egypt, Iraq, Turkey, and Persia to be under his care. In the absence of any system of certification, cases are received in the early stages, and the results of treatment have been remarkable.

Henry Watson Smith was born near Aberdeen on February 6th, 1879, of Scottish parents. Having entered as a medical student at the University of Aberdeen he won several bursaries and gold medals, and graduated M.B., Ch.B. with honours in 1901. After holding house appointments at Aberdeen he was house-surgeon at the West Suffolk General Hospital, Bury St. Edmunds, for two years, then for eighteen months at Peckham House, London, and for the following three years second assistant medical officer at the Durham County Mental Hospital. It was on the strong recommendation of the last-named body that the London Committee chose him as the future head of its hospital on Mount Lebanon, and he took up his official duties in February, 1909, having first obtained the Turkish medical degree at Constantinople, since Syria was at that time under the Turks. Subsequently he added to his knowledge of French a thorough working knowledge of Arabic. His thesis on the aetiology and pathology of general paralysis of the insane gained him the M.D. Aberd. in 1912, but beyond

that he wrote little, for the time he could spare from the work of the hospital was devoted to teaching medical students at the (American) University of Beirut. He was appointed professor of psychiatry and neurology in 1926, and thenceforward held regular classes, both in Beirut and at the hospital six miles away. This teaching side of his work was the more important, since thirty-five years ago, when the hospital was founded, any care for mental sufferers in Syria was non-existent, beyond the cruel rites of exorcism practised by religious fanatics. The change of attitude in this matter in a generation has been revolutionary, and, apart from the actual results of treatment, the ideas for which Asfuriyeh has stood, and the example which it has set of scientific and humanitarian ways of thought and of treatment, have lifted it to a unique place in the country. In this result the personality of the director played a great part. Dr. Watson Smith is said to have been the only British subject allowed to remain in Syria during the war, and had it not been for the representations made to the Turks by him and his executive committee—that the hospital was international ground—being "wakf," or dedicated to the use of mental sufferers of all nationalities in Syria—there is no doubt that Jemel Pasha would have carried out his intention of using the hill on which it stands for gun emplacements. As it was, he respected the site as a religious foundation, and authorized a certain supply of food, which kept alive most of the patients and staff during the war, when other civilians perished all around, by the thousand, of famine. In 1917, when the victorious British troops arrived, the director was able to receive and treat a large number of General Allenby's men at the hospital during a serious epidemic of influenza, in recognition of which he received the O.B.E. It was perhaps after this time that he began to show his special qualities as an administrator. Out of the meagre funds obtainable for some years from Europe and America, he contrived to restore and re-equip the buildings and develop the thirty-six acres of land, so that by 1924 the place was ripe for expansion. Pavilion after pavilion has been built, under his personal supervision, without architect or contractor, also a model steam laundry: an artesian well of 400 feet was bored and a scheme of olive planting, olive pressing, and soap making started. In November last came the crowning achievement—to be able to build a new house for women entirely out of local funds. The Scottish house was opened in November last by the President of the Lebanese Republic, and this event and the completion of Dr. Watson Smith's twenty-fifth year of service were marked by the bestowal upon him of the highest decoration given to a foreigner—the Médaille d'Honneur du Mérite libanais du deuxième classe.

The death took place, in a nursing home at Edinburgh on June 10th, of Dr. JOHN MACKAY of Dall-Avon, Aberfeldy, Perthshire. Dr. Mackay was born in 1847, and after receiving his medical education partly in Aberdeen and partly in Edinburgh he qualified L.R.C.P., L.R.C.S. at Edinburgh, and graduated M.B. at Aberdeen in 1875. He proceeded to the M.D. of Aberdeen in 1879. After a short time as assistant in a Durham practice he became assistant to the late Dr. Irvine Pitlochry. In 1880 he began practice at Aberfeldy as successor to the late Dr. Reid. Here he worked for over half a century, and, in addition, acted as medical officer of health for the burgh of Aberfeldy, and as parochial medical officer for the parishes of Logierait and Dull. He was also medical officer for the combination poorhouse of Atholl, Weem, and Breadalbane. Dr. Mackay was a keen member of the British Medical Association, and served a term as president of the Association's Perthshire Branch. He took a great interest in local public affairs; for many years he was a member and chairman of the School Board of Dall Parish. He was an early supporter of the Volunteer move-

ment, and maintained his connexion with the Volunteer Force for a number of years, retiring ultimately as Surgeon Colonel of the Fifth Volunteer Battalion of the Royal Highlanders (Black Watch). The interment took place at Aberfeldy cemetery on June 13th.

Dr. VINCENT WING TWINING, who died at Ryde on June 6th at the age of 73, was the youngest son of the late Dr. Edward Twining of Walthamstow. He received his medical education at Aberdeen, where he graduated M.B., C.M. in 1886. He was also a student at the Rotunda Hospital, Dublin. In 1893 he started practice at Llanwrtyd Wells, but removed to Salcombe in the following year on the death of his brother, Dr. A. H. Twining. There he remained until 1920, when he retired from general practice, and received various testimonials of friendship and appreciation from his colleagues and patients. He subsequently did occasional locum tenent work while his health permitted. Dr. Twining was for many years a member of the British Medical Association. His only son was killed in the war, but he is survived by his widow and a married daughter, who is also a member of the medical profession.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

The House of Commons this week passed the Finance Bill through report and read the Petroleum Production Bill a second time. The Estimates for the Ministry of Health and the Ministry of Labour were discussed. On the former, discussion was expected on water supplies and on slum clearance.

The Protection of Animals (Cruelty to Dogs) (Scotland) Bill was read a second time in the Lords on June 13th, and the Workmen's Compensation (Coal Mines) Bill a third time on June 14th.

The Statutory Salaries (Restoration) Bill was read a third time in the Commons on June 13th, and a first time in the Lords on June 14th.

The Gas Undertakings Bill was read a third time by the Commons on June 15th. It contains provisions against the imposition of conditions in leases or otherwise to prevent tenants of houses from receiving supplies of gas.

The House of Lords, on June 19th, read the Betting and Lotteries Bill a third time and the Statutory Salaries (Restoration) Bill a second time. The Unemployment Bill and the Licensing (Permitted Hours) Bill both passed through report.

On June 4th Lord Mamhead presided over a conference representing local authorities, medical organizations, newspaper proprietors, advertising agents, pharmaceutical manufacturers, distributors, vendors, and others interested to consider the Advertising of Medicines Bill, drafted by a committee under the chairmanship of Captain G. S. Elliston. All these interests reached a greater measure of agreement than had been attained hitherto. Several points were referred back to the drafting committee for further consideration. Until these have been settled no decision will be taken on the introduction of the Bill in the House of Lords or the House of Commons.

Compensation to Hospitals

Consideration of the Road Traffic Bill was resumed by a Standing Committee of the House of Commons on June 14th. A new clause dealing with remuneration for treatment, other than emergency treatment, rendered by hospitals, was brought up by Mr. Storey, who moved that the clause be read a second time. Its text was:

(1) Subject to the provisions of this Section where medical or surgical treatment is rendered to any person in any department of a hospital whether as an in-patient or as an out-patient in respect of bodily injury (including fatal injury) caused by or arising out

of the use of a motor vehicle on a road or in a place to which the public have a right of access the owner of the vehicle shall pay to such hospital the expenses reasonably incurred by the hospital in affording such treatment (other than emergency treatment within the meaning of Section (1) of the Road Traffic Act, 1933, in respect of emergency treatment of injuries arising from the use of motor vehicles on roads) of this Act after deducting from such expenses any moneys actually received by the hospital in payment of a specific charge for such treatment (other than emergency treatment as aforesaid) not being moneys received under any contributory scheme. Provided that the amount to be paid under this Section shall not exceed £50 for each person in respect of treatment as an in-patient and £5 for each person in respect of treatment as an out-patient.

(2) Liability incurred under this Section by the owner of a vehicle shall, where the event out of which it arose was caused by the wrongful act of another person, be treated for the purposes of any claim to recover damage by reason of that wrongful act as damage sustained by the owner.

(3) A policy of insurance or a security in respect of third-party risks shall not be deemed to comply with the requirements of Part II of the principal Act unless the owner of the vehicle to which it relates is specified therein for the purposes of paragraph (b) of Subsection (1) of Section thirty-six or of Section thirty-seven of the said Act, as the case may be, and notwithstanding anything in the proviso to paragraph (b) of Subsection (1) of Section thirty-six of the principal Act any liability which may be incurred under this Section by the owner shall be deemed to be a liability required to be covered under that paragraph.

(4) A chief officer of police shall, if so requested by a hospital who allege that they are entitled to claim a payment under this Section, furnish to that hospital any information at the disposal of the chief officer as to the name and address of the owner and the identification marks of any motor vehicle which that hospital allege to be a vehicle out of the use of which the bodily injury arose, and as to the name and address of the authorized insurer who has issued a policy of insurance, or of the body or person who has given a security or made a deposit in relation to such vehicle.

(5) A sum payable under this Section shall be recoverable as if it were a simple contract debt due from the owner of the vehicle to the hospital.

(6) For the purposes of this Section the expression "hospital" means an institution (not being an institution carried on for profit) which provides medical or surgical treatment for in-patients; and the expression "expenses reasonably incurred" means (a) in relation to a person who receives treatment at a hospital as an in-patient an amount for each day such person is maintained in such hospital representing the average daily cost for each in-patient of the maintenance of the hospital and the staff thereof and the maintenance and treatment of the in-patients therein, and (b) in relation to a person who receives treatment at a hospital as an out-patient the reasonable expenses actually incurred.

(7) Subsection (2) of Section thirty-six of the Principal Act as amended by Section thirty-three of the Road and Rail Traffic Act, 1933, is hereby repealed.

Mr. STOREY explained that the clause provided for payment of hospital treatment, other than emergency treatment, up to a maximum of £50 for in-patients and £5 for out-patients, irrespective of the question of negligence. He contended that if the emergency treatment clause which the committee had previously passed was justified (reported in these columns on June 16th) it was even more right that treatment which cost the hospitals tens or hundreds of pounds should be met in this way. He submitted that the clause did not attribute the whole fault of accidents to the motorists. It provided that the cost of treatment should be borne, not by the hospital or by the patients who were not responsible for the change in road conditions, but by the motorist who was responsible for the change. Where it could be proved that some other party was directly responsible for the accident the clause gave the motorist the right of recovery. The compulsory insurance clauses of the Road Traffic Acts provided a means whereby the cost of treatment could be met without any appreciable burden being placed on individual motorists, and also a means by which payments for treatment could be distributed among the hospitals which rendered it. The clause adopted the analogy of workmen's compensation, where compensation was recoverable without proof of negligence on the part of the employer. In workmen's compensation such a breach of the principle that a man was liable only for his own negligence was felt to be the less of two evils, and in road accident treatments it would be the same. The increase in accidents costs the hospitals some £180,000 per annum. With the limit of £50, which the clause proposed, the sum which could be recovered would not amount to so much as £180,000, but even if that whole sum were recovered it would work out at only 1s. 7d. per head per motorist. After long experience as chairman of a hospital and of its finance committee he did not accept the argument that the cost of treating road accidents was

met by subscriptions from motorists to hospitals. He did not believe that if the clause passed the hospitals would lose a penny in subscriptions. At present workmen subscribers to hospitals felt a grievance because money raised by them to treat the sick of the district was used for road accident cases. In the considered opinion of the representatives of the hospitals the present clause was a fair and simple solution of the problem, but if the Minister could not accept it Mr. Storey asked him to suggest an alternative. Mr. Storey also mentioned that another precedent for ignoring the principle that a man was liable only for his own negligence was found in the Air Navigation Act of 1920.

Sir F. FREMANTLE said there were other analogies also on this point. The Select Committee appointed by the House of Lords to consider the Bill promoted by Lord Moyrihan and that promoted by Lord Danesfort had cited several, including the law of collision of two ships. Sir Francis said the strong feeling on the subject throughout the country had resulted in this clause. He hoped that if the Minister had not an alternative ready he would show he was prepared to help the hospitals to find a solution. Sir E. GRAHAM-LITTLE stated that the request for the clause came from all the authoritative bodies which dealt with the hospitals: King Edward's Hospital Fund had estimated the cost of a bed to a hospital to be roughly five guineas a week, to which overhead charges would add another guinea, even though there was no charge for professional treatment. Some hospitals might do it for three to four guineas per week, but the larger hospitals had an extensive system of special departments. So far from hospitals being supported by the contributions of rich people the general hospital at Coventry had five-sixths of its running costs defrayed by the workmen's associations of that town.

Mr. STANLEY asked the committee to come to a decision. He naturally felt sympathy for hospitals, but he protested against the suggestion that members who did not support the clause might be called to account by their constituents. On the clause with respect to payment to doctors he had warned the committee what would happen if a breach were made in the principle of responsibility for accident. The clause would select the motor owner as almost the only class in the country to be held responsible for an act not in any way neglectful, and, indeed, possibly caused by the negligence of someone else. He had previously told the committee that as an isolated case the practical injustice to the doctor was greater, but it was impossible to regard the doctor's case as an isolated incident in view of the further pressure to which the committee was subjected. The Bill was intended to deal with accidents on the road, and to secure among motor users a standard of conduct to which they would adhere voluntarily and not under the compulsion of the law. If motor users were to be regarded as always at fault they could not hope to build up among them the spirit which they desired. He dismissed, as unfair, the argument that the coming of the motor had put this responsibility on the hospitals, and therefore the motor owner should pay. By the invention of the internal combustion engine the hospitals had received hundreds of thousands of pounds through the generosity of such men as Lord Nuffield, and they could not ignore all the credit which was due to motors. To ordinary subscribers to hospitals the clause would mean the end of the voluntary hospital system as they understood it. If they were to be taxed to provide for the care of certain injured people if the injury arose in a special way, many subscribers would feel that they would in future limit their subscriptions by whatsoever return the hospitals could give them. In reply to the request that he should suggest an alternative, Mr. Stanley asked if the members who pressed the clause had ever tried appealing to motorists as a class. Had there ever been an attempt by the hospitals as a whole to try, with the help of motoring organizations and motorists generally, to set up a central fund from which relief could be given? Mr. TUKROS said all the associations of hospitals in Yorkshire had appealed to motorists. Mr. STANLEY continued that he believed the immediate result from such an appeal would be better for the hospitals, and in the long view their future would be more assured. He believed that co-operation with the motoring interest would be much better advised than a method which, in fact, was nothing else but a tax upon motorists as a class.

Sir GIFFORD FOX said he came from a corridor constituency where an abnormal number of beds were occupied

by road accident cases. Last year the Hanley District War Memorial Hospital admitted twenty-two such cases, three of which were fatal. These involved a total of 564 days in hospital. The cost of their treatment was £237, of which £29 was received from insurance under the Road Traffic Act and third-party risk, and £73 from other sources, so that the net cost to the hospital was £135. About 10 per cent. of the beds occupied in the year were used for motor accident cases, and only 12½ per cent. of the cost was recovered. He put his name to the clause because he felt it was the opinion of the community. If, as the Minister suggested, a central fund was set up, why could not a grant be made from the money paid by motor owners in taxation? Mr. TURTON considered it was wrong for Parliament to give 12s. 6d. to the doctor for emergency treatment and not to deal with the great loss which hospitals were suffering all over the country. Mr. STANLEY asked whether Mr. Turton would say that, having passed the hospitals clause, the committee must extend the principle in the case of an injured man treated in his own home. Mr. TURTON replied that there was a legal liability on members of a family to support a relative, as was made plain in the Lunacy Act. He rested the case of the hospitals not so much on legal liability as on grievance. Doctors had rich patients as well as poor, but some hospitals on main roads were so filled with accident cases that they could not take any paying patients. Co-operation, Mr. Turton continued, had already been tried. A large association in the North of England was presided over by Lord Harewood for that object. Money had been obtained for hospitals, but not nearly enough.

Sir JOSEPH LAMM appealed for the clause to be withdrawn. Mr. ALLAN REID, who said he had been twenty-eight years on the board of management of voluntary hospitals in his constituency, hoped that some way would be found to compensate both doctors and hospitals other than that suggested in the clause. He believed that if the principle were adopted it would be the first stage towards the extinction of the voluntary hospital. Mr. GUY said machinery was already set up under the Road and Rail Act for payment to hospitals for treatment of out-patients or in-patients. That was only where negligence was admitted or proved. The proposal was to use the same machinery but to make the payments irrespective of negligence. He had asked the Edinburgh Royal Infirmary how the existing machinery under the Road and Rail Traffic Act worked. It had been able to recover the cost of treatment in about half the cases, but encountered difficulty in cases where there was a doubt as to negligence. In these the insurance companies offered the injured person £25 without any admission of liability, and said that was conditional on the hospital withdrawing its claim. That put the hospital in an unfair position, because if the hospital insisted on claiming, the injured person did not get a penny unless he fought the action in court, and so he put the blame upon the hospital. He thought the Minister would agree that this point should be provided for. He understood that before long an "omnibus" hospital Bill might be introduced, and he asked the Minister to consider whether some new remedy for this difficulty could not be provided in such a Bill.

Mr. STANLEY replied that in the discussion certain principles had been propounded which he looked upon as extremely dangerous, particularly the statement that once the committee accepted the doctor's clause the door was wide open for every extension of the principle that lack of negligence was no defence. He must make it clear that if the clause was withdrawn that action was not taken because he had promised some concession in the future. He was not bargaining for the withdrawal of a clause which raised a wrong principle. Mr. STONEY said, in withdrawing the clause, he and his friends did not take back what they had said. They merely made their appeal to the Minister.

On the motion that the clause be read a second time the clause was defeated by 21 to 6.

A clause dealing with hours of duty and periods of rest for employees driving motor vehicles was moved and withdrawn. A clause to restrict pillion riding, and the carriage of second persons on pedal bicycles not specially fitted for such transport, was moved and added to the Bill.

The Bill was then reported to the House, consideration on committee having been completed.

Hours of Shop Assistants

Discussion of the Shops Bill was resumed in the House of Commons on June 14th before a Standing Committee. Mr. RHY'S DAVIES moved to leave out the provision in Clause 2 postponing for two years the introduction of a forty-eight-hour week for young persons employed in or about shops. He proposed to substitute the date June 30th, 1935. Mr. HACKING said the clause provided that in the transitional period of two years the maximum normal working hours should be fifty-two. The absolute limit, including permitted overtime, would be sixty hours in one week, which could not be worked on more than three occasions in the year. The committee rejected Mr. Rhys Davies's amendment by 18 votes to 3, but on the motion that Clause 2 stand part of the Bill the whole clause was deleted by 11 to 10. Mr. HACKING said the Government would ask the House during the report stage to restore the clause.

Consideration of the Bill was resumed in Standing Committee on June 19th. Clause 3 prohibits the employment of young persons between the hours of 10 p.m. and 6 a.m., except those engaged in the distribution of milk and bread, who are allowed to begin work at 5 a.m. The committee, by a majority of 17 to 9, gave the same exemption to distributors of newspapers. The committee adjourned until June 21st.

Aniline Dyes in Meat Marketing.—Dr. O'DONOVAN moved, in the House of Commons on June 7th, that an address be presented against a draft Order in Council under the Merchandise Marks Act, 1926, which was presented to the House on May 8th, 1934. He explained that this Order enjoined that imported frozen or chilled meat should bear an indication of origin branded or stamped, stencilled, or printed in ink or stain, durably and conspicuously, in letters not less than half an inch in height, at distances, in the case of chilled beef, of two inches in a line from the hock joint to the neck. This brand would withstand cooking, and would affect the appearance of the food, which was pleasurable to the healthy and necessary to the sick. A Government expert had given evidence that this meat might be stained with aniline dyes, dissolved in methylated spirit. If every butcher handling frozen mutton or beef appeared before his doctor every time he had a rash and complained it was due to aniline dye, the woes of all who had to sign certificates would be trebled. If a medical man suspected that a consumer of frozen meat had a stomach-ache due to aniline, the doctor would be compelled to notify the case at once under the London County Council General Powers Bill, which the House had lately passed. Dr. ELLIOT said the method of marking was already applied to home produce. There was no satisfactory alternative to marking the meat itself. The Order did not involve the use of aniline dye, and he had reason to suppose that soon after it came into force some such device as roller-marking by electricity would be in operation and would not involve the use of dyes. Dr. O'DONOVAN asked leave to withdraw his motion, but a division was challenged and the Order was approved by 95 to 22.

Malaria Outbreak in Bechuanaland.—Replying to Mr. Lunn, on June 13th, Mr. J. H. THOMAS stated that there had been an outbreak of malaria in districts of the Bechuanaland Protectorate. He had not received any detailed reports from the High Commissioner for South Africa as to mortality, but had no doubt these would be forthcoming as soon as the information was available. Prompt measures had been taken by the local administration to deal with the outbreak by sending medical officers and the necessary supplies of quinine to districts affected. Provision was made last year and this year for the relief of distress occasioned in the Protectorate by the disastrous drought in South Africa.

Research into Native Mentality in Kenya.—On June 13th Sir P. CUNLIFFE-LISTER told Dr. O'DONOVAN that he still awaited the views of the Governor of Kenya on the suggested research into native mentality on lines indicated by Dr. H. L. GORDON. He expected that the Governor would desire to consult his advisers.

Health of Children entering Elementary Schools.—Mr. RAMSBOTHAM told Viscountess Astor, on June 14th, that in the year 1933 95,328 children, or 16.3 per cent. of the children entering public elementary schools, whether at the age of 5 or earlier, were found to be in need of treatment for various defects, excluding uncleanness and dental disease. Information was not available in respect only of children entering at 5, or as to the number or percentage of entrants suffering from defects requiring observation.

Vermis in Transit to Housing Estates.—In reply to Mr. Caporn, on June 14th, Sir HILTON YOUNG stated that the Public Health Act, 1925, made provision for the compulsory cleansing by local authorities of premises used for human habitation which were infested with vermin, and for the cleansing, disinfecting, and, if necessary, destruction of verminous articles found in any such premises. He had no reason to suppose that these powers were inadequate. There was no power to deal with articles which were verminous when they were in transit to housing estates; he considered it more practical to catch them before they were removed. He had recently issued to local authorities a circular and memorandum on disinfestation.

Country Districts and the Drought.—Replying to Major Carver on June 14th, Sir HILTON YOUNG said that rain-water, with proper storage, provided a reasonably adequate supply of water in country districts where other supplies were impracticable. He was issuing a leaflet on measures for conserving rainwater. Where emergency due to drought arose, local authorities and other water undertakers, in co-operation with the Ministry of Health, took measures to meet it by fresh supplies and emergency methods of distribution, which were suitable to the special needs of the locality, and varied greatly. The engineering inspectors of the Ministry advised on the measures to be taken. Local authorities' schemes for boreholes for common use were eligible for grant, but to provide separate waterworks for individual houses was not properly a public service.

Road Accidents: Negligence Against Dead Persons.—The Law Reform (Miscellaneous Provisions) Bill, which had passed the House of Lords, was considered by the Commons on June 15th. Sir DAVID SOMERVELL, Solicitor-General, moved the second reading. He explained that it was based on recommendations by a committee set up by the Lord Chancellor, and was intended to remedy hardships resulting from the old legal principle that a personal action died with the person. The Bill laid down that all causes of action subsisting against or vested in a deceased person, except for defamation or seduction, should survive or against or for the benefit of his estate. The real urgency of the Bill was to deal with street accidents. The injured person would have the same rights where the negligent motorist was killed as at present where the motorist survived. The Bill also covered cases where the injured person subsequently died. Subject to exceptions and safeguards there would in that case be cause of action. Mr. RHYS DAVIES protested against the proviso that the Bill should not apply to Scotland. The Bill was read a second time.

Protective Measures in Gas Warfare.—Replying to Mr. Kirkwood, on June 18th, Mr. DUFF COOPER said that training in defence measures against gas attacks, whether from the air or otherwise, was part of the normal training of the Army. The voluntary aid detachments provided by the British Red Cross Society undertook to assist the medical services of the Army should they be required in time of emergency, and measures of protection in gas warfare formed part of the training given to those detachments. Army officers were accordingly allowed to assist in this training by giving lectures. Mr. Kirkwood's question averred that Army officers had given lectures at Maryhill Barracks, Glasgow, to members of the Red Cross and voluntary aid detachments on how to deal with victims of gas attack from the air.

Notes in Brief

The number of persons in receipt of poor relief in England and Wales on May 26th, 1934, excluding rate-aided patients in mental hospitals, persons in receipt of domiciliary medical relief only, and casuals, was 1,349,707. The corresponding number on May 27th, 1933, was 1,286,640.

The report of the chief inspector of factories and workshops for 1933 will be issued in the middle of July.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Appointments Committee of the Faculty of Biology "B" will shortly proceed to appoint two Demonstrators in the Department of Anatomy, whose duties will commence on October 1st, 1934. Applications are invited from candidates with laboratory experience, particularly in anatomy, physiology, pathology, embryology, or radiology. Facilities will be provided for research in anatomy and related branches of the subject. Particulars as to stipend and duties may be obtained from the Secretary General of the Faculties, The Registry, Cambridge, to which address applications should be sent by July 1st.

At a congregation held on June 16th the following medical degrees were conferred:

M.B., B.CHIR.—T. W. Smailes.

M.B.—J. S. Mitchell.

B.CHIR.—C. P. F. Boulden, S. A. Probert.

• By proxy.

UNIVERSITY OF BRISTOL

The following candidates have been approved at the examinations indicated:

M.D.—H. Rogers (with distinction); F. H. Bodman, J. J. J. Giraldi, N. L. Price.

CH.M.—G. F. Langley (with distinction).

FINAL M.B., CH.B.—Part I: M. A. Nicholson, B. Ridgway. Part II: A. C. Molden (first-class honours with distinction in surgery, obstetrics, and public health), A. G. W. Branch (second-class honours with distinction in obstetrics), Rosalind M. S. Derham (second-class honours with distinction in public health), C. H. G. Price (second-class honours), Grace J. V. Ball, Dorothy E. Barber, Violet Fry, N. Greenberg, G. L. L. Gurney, T. R. V. Gurney, Gwladys R. Llewellyn, R. A. Mathews (with distinction in surgery and public health).

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

A meeting of the Council of the Royal College of Surgeons of England was held on June 14th, when the President, Sir Holburt Waring, was in the chair.

Appointments

The President reported his appointment of Professor William Wright as Thomas Vicary Lecturer.

A letter was read from Mr. Alan Newton, Censor in Chief of the Royal Australasian College of Surgeons, reporting the following nominations by the council of that College for the Primary Fellowship Examination, to begin in Dunedin, N.Z., on November 29th, 1934:—Assessor in Anatomy: Professor W. P. Gowland, F.R.C.S. Assessor in Physiology: Professor John Malcolm. Appointed to act as superintendent of the examination: Mr. Herbert Chapman, Registrar of the University of Otago.

Examiners

The following examiners were elected for the ensuing year:

Fellowship—Anatomy: J. B. Hume, Grant Massie, G. Gordon-Taylor, P. N. B. Odgers. **Physiology:** G. A. Buckmaster, D. H. de Souza, S. Wright, H. Hartridge.

Under the Conjoint Board—Elementary Biology: T. J. Evans, G. P. Mudge, C. C. Hentschel, A. J. Grove. **Anatomy:** W. E. Le Gros Clark, H. A. Harris, E. P. Stibbe. **Physiology:** A. St. G. J. McC. Huggett, Samson Wright. **Midwifery:** L. C. Rivett, M. Donaldson, A. C. Palmer, V. F. Lack. **Pathology:** C. E. Shattock, R. Davies-Colley, R. G. Canti, J. McIntosh. **Diploma in Public Health:** Part I, C. C. Okell; Part II, J. Fenton. **Diploma in Tropical Medicine and Hygiene:** Pathology and Tropical Hygiene, D. S. Harvey; Tropical Medicine and Surgery, G. C. Low. **Diploma in Ophthalmic Medicine and Surgery:** Part I, Sir Stewart Duke Elder, C. B. Goulden; Part II, R. F. Moore. **Diploma in Psychological Medicine:** J. G. Greenfield. **Diploma in Laryngology and Otology:** Part I, E. M. Woodman, S. R. Scott; Part II, T. B. Layton. **Diploma in Gynaecology and Obstetrics:** J. D. Barris. **Diploma in Medical Radiology:** Part I, J. M. Woodburn Morison; Part II, J. H. Douglas Webster.

Dental Surgery (Surgical Section)—R. J. Howard, C. E. Shattock, C. P. G. Wakeley, P. H. Mitciner, E. G. Slesinger, R. M. Vick.

Fellowship

Diplomas of Fellowship were granted to the following thirty-six successful candidates at the recent examination:

G. F. ... R. W. Doyle, W. Buckley, W. A. ... W. Holmes, C. E. P. Markby, J. K. ... W. C. Oldfield, G. T. Partridge, E. A. ... R. S. Lewis, H. R. Thompson, H. F. Moseley, H. J. B. Atkins, R. G. Pulvertaft, A. Hilmy, K. S.

Ayyar, D. B. McGavin, J. R. Vaid, R. D. Ayyar, S. Sunkavally, F. N. Chenhall, E. J. Collins, J. V. Guinane, A. I. Hunter, S. Krantz, J. P. F. Lloyd, A. Legan, C. J. Lord, S. B. Morris, D. G. Radcliffe, E. B. Whittingham.

Membership

Diplomas of membership were granted to H. C. Hugh, B. L. E. Wong, A. T. Roden.

APOTHECARIES' SOCIETY

In connexion with the International Conference on the Standardization of Vitamins meeting last week in London, under the auspices of the Health Committee of the League of Nations, the Master (Dr. J. O. Wakelin Barratt), the Wardens, and the Court of Assistants of the Society of Apothecaries of London, held a reception at their Hall in Blackfriars on the evening of June 14th. Invitations were issued to various British workers in the field of vitamin research, and to physicians and physiologists who desired the opportunity of meeting the research workers attending the conference. Among the latter who attended the reception were: Professor E. Mellanby (Medical Research Council), Professor J. C. Drummond (University College), Professor H. von Euler (Stockholm), Professor L. S. Fridericia (Copenhagen), Professor B. C. P. Jansen (Amsterdam), Professor R. di Mattei (Pavia), Dr. E. M. Nelson (Washington, U.S.A.), Mme Randoim (Paris), Professor H. Steenbock (Wisconsin, U.S.A.), Professor A. Szent-Gyorgyi (Szeged), Dr. W. R. Aykroyd (League of Nations, Geneva), Dr. Harriette Chick (Lister Institute of Preventive Medicine), Professor J. C. G. Ledingham (Director of the Lister Institute), Dr. K. Coward, Professor A. Jung (Basel), and Dr. C. Lormand (Paris).

Medical News

The Board of Control (Caxton House, West, Tothill Street, S.W.1) has issued a revised list of medical practitioners in England and Wales who have been approved by the Board for the purpose of making recommendations under Sections 1 (3) and 5 (3) of the Mental Treatment Act, 1930. The names are given first in alphabetical order with full addresses, and are then regrouped geographically.

The annual general meeting of the Feyer Group of the Society of Medical Officers of Health will be held at 1, Upper Montague Street, W.C., on Friday, June 29th, at 4 p.m., when Professor Ulrich Friedemann will read a paper on "Malignant Diphtheria, with Observations on Cardiovascular Failure and Methods of Treatment." A meeting of the council of the group will be held at 3 p.m.

The annual meeting of the National Institute for the Deaf will be held in the Library, Baptist Church House, 4, Southampton Row, W.C., on Wednesday, June 27th, at 3 p.m., when Lord Charnwood will preside and give an address.

The Institute of Malariology, directed by Professor Bastianelli, has arranged a post-graduate course from July 16th to September 6th for Italian practitioners, and from July 10th to September 10th for foreigners, when lectures will be given by S. R. Christophers, S. P. James, G. Pittaluga, N. H. Swellengrebel, and Warrington Yorke. The fee is 200 lire. Further information can be obtained from the Society of the Institute, Policlinico Umberto I, Rome.

The Fellowship of Medicine announces that the next lecture-demonstration, in the series being given at 11, Chandos Street, W., will take place on June 26th at 2.30 p.m.; subject, "Nephritis." There will be no lecture on July 3rd, but the series will resume on July 10th; subject, "High Blood Pressure." There will be a week-end course in medicine and surgery at the Metropolitan Hospital, Kingsland Road, on June 30th and July 1st, and a week's course in ophthalmology at the Central London Ophthalmic Hospital from July 2nd to 7th. A week-end course in general medicine and surgery has been arranged at the General Hospital, Southend-on-Sea, on July 7th and 8th. Other forthcoming courses include urology at All Saints' Hospital, July 9th to 28th; dermatology at the Blackfriars Skin Hospital, July 9th to 21st.

A demonstration of dermatological cases will be given by Dr. O'Donovan at the National Temperance Hospital on July 14th at 3 p.m.

The British Health Resorts Association is holding a conference at Cromer and Sheringham from June 29th to July 1st, by invitation of the respective urban district councils and the local medical profession. There will be two discussions: one on "The Seaside Resort in the Treatment of Respiratory Diseases," opened by Dr. R. A. Young, followed by Dr. L. S. T. Burrell and Dr. A. J. Morland; and the second on "Climatic and Allied Factors in the Incidence of Disease and its Treatment on the East Anglian Coast," opened by Dr. R. Fortescue Fox, followed by Dr. F. W. Burton-Fanning, Dr. Wilfred Pearson, and Mr. L. C. W. Bonaciua.

Dr. O. Leaser of Stuttgart will give an address on "Constitution and Constitutional Treatment" at the London Homoeopathic Hospital, Queen Square, W.C., on Thursday, June 28th, at 5.30 p.m. Medical men and women wishing to attend are asked to notify the honorary secretary of the British Homoeopathic Society at the hospital.

The joint conference of the Federation of Cremation Authorities in Great Britain and of the National Association of Cemetery and Crematorium Superintendents will be held in the Council House, Birmingham, from June 25th to 28th. Sir John Robertson, M.D., and Sir Gilbert Barling, Bart., F.R.C.S., will contribute papers.

An International Congress of Medicine applied to physical education and sport, and organized by Professor Latarget, president of the International Association of the Medicine of Sport, will be held at Vittel from September 2nd to 4th under the presidency of Professor Paul Carnot. Further information can be obtained from the general secretary, Dr. Boigey, Société Générale des Eaux, Vittel, Vosges.

In a *Nature* of June 16th H. Dam of Copenhagen describes a haemorrhagic condition in chicks closely resembling scurvy. As vitamins A, D, B, and B₂ were present in the experimental diet, and as vitamin C had no effect in controlling the symptoms, he concludes that the cause of the disease is a deficiency in an antihæmorrhagic factor different from vitamin C and occurring in cereals and seeds.

The issue of *Rassegna Internazionale de Clinica e Terapia* for April 30th is devoted to a description of the mineral spas of Italy.

The issue of *Medizinische Klinik* for June 8th contains a sympathetic obituary notice of Dr. William Welch by Professor W. Kolle of Frankfurt.

The Trustees of the Lady Tata Memorial Trust, on the recommendation of the Scientific Advisory Committee, announce the award of the following international scholarships, each of the value of £400, for the academic year 1934-5, for research work in diseases of the blood, with special reference to leukaemias: Dr. W. Büngeler (Danzig), Dr. L. Doljanski (Copenhagen), Dr. M. C. G. Israels (Manchester), Dr. C. Oberling (Paris), Dr. J. Engelbreth-Holm (Copenhagen), Dr. M. O. K. Jørgensen (Aarhus, Jutland, Denmark), Dr. R. Meier (Leipzig), and Dr. Lucy Wills (London).

The King has appointed Dr. J. Cran, O.B.E., V.D., to be a Member of the Executive Council of the Colony of British Honduras.

The following medical men were called to the Bar on June 13th: Dr. W. D. R. Thompson (Inner Temple), and Dr. W. A. McE. Stewart (Middle Temple).

The Nobel prize for literature for 1933 has been awarded to the Finnish novelist, F. E. Sillampee, who is a doctor of medicine, aged 45.

A Hispano-American Association for Medico-Biological Studies has recently been founded at Madrid, with Dr. Collazo of Uruguay as president and Professor Pittaluga of Spain as vice-president.

There has been a reduction of 35 per cent. in the number of fatal accidents in the New York State industries during the last four years.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, *British Medical Journal*, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EUSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE *BRITISH MEDICAL JOURNAL*, *Aitology Westcent, London*.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westcent, London*.

MEDICAL SECRETARY, *Mediscera Westcent, London*.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62550 Dublin), and of the Scottish Office, 7, Drumshugh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Guava Leaves for Dysentery

"W. G. T." writes: Has any reader, with South African experience, knowledge of the treatment of dysentery with a decoction of guava leaves? I am given to understand that it is extensively used by the natives, and should like to know the strength and dosage used, and also if there are any harmful effects.

Insect Bite Causing Gangrene of Finger

Dr. EDWARD C. B. INOTSON (Jersey) writes: A very healthy man, aged 33, while picking gooseberries on June 10th, was bitten on the tip of the right index finger by a small black beetle; it was tiny, but stuck its proboscis in deeply, requiring force to remove it. He did not preserve the beetle. He came to me on the 13th. There was a sulcus in the finger and a ring of gangrenous skin surrounding and constricting the end of the digit, great pain, and swelling of the proximal end. I applied a kaolin poultice. On the 15th I divided the thick band of gangrenous skin which was strangling the finger. Kaolin was continued. On the 16th there was much improvement. Has anyone met with a similar case? And what is the creature which causes dry gangrene? I have never before encountered such a case.

Vaccine Treatment of Pertussis

Dr. GEOFFREY DUDLEY (Stourbridge) writes: In the *Journal* of June 9th (p. 1047), in the reports of societies, Dr. W. Gunn, discussing whooping-cough, is reported to have said that "Vaccines prepared from the Bordet-Gengou bacillus had proved useless—and occasionally dangerous—in treatment." I have used vaccine for treatment in many cases, apparently with success, and certainly without ill effect, but I should be glad to know what the possible dangers are.

Pruritus with Jaundice

Dr. S. LEIGH COX (Torquay) writes, in answer to the inquiry made by "P. J. M." in the *Journal* of June 16th, with reference to intolerable itching caused by jaundice: I have found that in similar cases the administration of calomel, 1/10 or 1/6 grain t.d.s., materially improves the pruritus. I usually recommend that the patient has a week "on" and a week "off" this regime, continuing the alternate-week system until relief is obtained. I find that small doses such as these are well tolerated, even where there is normally an idiosyncrasy to calomel.

Dr. F. B. JULIAN (Liverpool) writes: I would suggest dolichos pruriens. I have been able to control this maddening symptom with this drug when no other measure had the slightest effect. The tincture may be obtained from Messrs. Nelson, 73, Duke Street, Grosvenor Square, London, W.1, in the 1x potency. The dose is two to three drops thrice daily in water.

LETTERS, NOTES, ETC.

Rellex Effects of Head Posture

Dr. A. MURDOCH (Bexhill) writes: Is any significance to be attached to the results of the experiments on the decerebrate animal, and, if so, can they be applied in any shape or form to the prevention and treatment of disease? The decerebrate animal is an automaton to all intents and purposes, as the conscious directing faculty has been destroyed, but it presents certain constant characteristics—namely, (1) a greater degree of tonicity of all the voluntary muscles of the body, producing a greater degree of rigidity throughout the body; (2) what is most striking—a responsiveness of any alteration of the position of the head in its relation to the spine. If it is true of the decerebrate animal that the position of the head in its relation to the spine produces these responses throughout the whole body, does it apply to the cerebrate conscious animal man? The decerebrate animal cannot alter the position of its own head, but cerebrate man can, and yet for all practical purposes man does not alter the poise of his head from its habitual static position when engaged in any activity. Is the reason for this to be sought in the decerebrate animal experiments—namely, that if he were to alter the relative position of the head to the spine he would automatically alter reflexly all the relationships of his body parts, and thus produce a condition which is so unfamiliar to him as to prevent him from doing easily, if at all, what he intended to do? If this is so—and it can be shown that bodily conformation and the relationships of the internal organs depend on the position of the head—then, by altering the position of the head, changes in the bodily conformation and relationships of the internal organs can be effected and used in the prevention and treatment of disease. I have been prompted to write this letter because of a personal experience. I wished to know if any change took place in the position of my own stomach after a barium meal, when I changed the position of my head from a forward and upward position to a backward and downward position. Dr. Overend, the radiologist to the Buchanan Hospital, St. Leonards, and to the Bexhill Cottage Hospital, watched the screen and then took two photographs on the same film. He noticed that the level of the stomach varied as much as three inches in the two positions. He also noticed that the bases of both lungs showed greater clearness in the first than in the second position. Can this be produced by anyone contracting his abdominal muscles without any reference to a change in the position of the head? Many practical questions might be asked of our physiologists, but the following appear to me to be of primary importance: Does it matter how anyone carries his head? Does the position of the head affect our bodily conformation and all our automatic reflexes? Does it affect the functioning of the abdominal parietes as an efficient abdominal support to the abdominal organs, to say nothing of the support of the abdominal blood pool? Has it any effect on the functioning and tonicity of the voluntary muscular system? Does it affect the movements of the thorax with corresponding effects on the lungs and heart?

Disclaimer

Dr. A. J. BYRNE (Leyton, E.10) writes to disclaim any responsibility for a laudatory reference to him by a patient, which has appeared in a local newspaper. The notice was published without his knowledge or consent.

"Indoxyluria and Indoxylaemia"

A Correction

The reference to the journal from which abstract No. 478, in our *Epitome* of June 16th (p. 93), was made was erroneously printed. It should read *Bull. et Mém. de la Soc. de Méd. de Paris*, April 13th, 1934, p. 247.

Mr. Henry Kimpton, medical publisher and bookseller, 263, High Holborn, W.C.1, has issued a new catalogue of second-hand works on urology, and will send copies to any reader who applies.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 38, 39, 40, 41, 42, 43, 46, and 47 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 44 and 45.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 332.

BRITISH MEDICAL JOURNAL

LONDON: SATURDAY, JUNE 30th, 1934

CONGENITAL HYPERTROPHIC STENOSIS OF THE PYLORUS AN ANALYSIS OF 145 CASES TREATED BY OPERATION

BY

H. L. WALLACE, M.B., CH.B., F.R.C.P.ED.

ASSISTANT PHYSICIAN, ROYAL EDINBURGH HOSPITAL FOR SICK CHILDREN

AND

L. B. WEVILL, M.B., CH.B., F.R.C.S.ED.

(From the Statistical Research Department, Royal Infirmary, Edinburgh)

In this paper an analysis has been made of 145 cases of congenital hypertrophic stenosis of the pylorus which have been treated by operation at the Royal Edinburgh Hospital for Sick Children during the twelve-year period 1922 to 1933 inclusive. In every case a positive diagnosis of pyloric stenosis was confirmed at operation, and no doubtful cases have been included in the series. Those treated by medical measures only, such as repeated gastric lavage, are not considered, although in a large proportion of the series treatment had been carried out in the medical wards prior to operation, with a view to improving the general condition of the patient. It is not proposed to discuss in detail the symptomatology of congenital pyloric stenosis, but merely to analyse the results of treatment in this series of hospital cases.

Sex and Age Incidence

Out of the total of 145 cases 125 were males and twenty females, representing a preponderance of males over females of 6.25 to 1. The 1931 census figures for

nized, is of great interest, as it is difficult to understand why a congenital malformation such as pyloric stenosis should show such a marked affinity for the male sex.

Graph 1 shows two curves: that with the unbroken line represents the age distribution on admission to hospital for the total cases, and the broken line shows the age at the first symptom. If these two tracings be compared, the interval elapsing between the first manifestations of the disease and the time when the condition was actually diagnosed will be obtained. It will be noted that in a large proportion of cases there was an interval of four weeks between the first manifestations and the admission of the child to hospital; in other words, there was a delay in treatment for this long period in a considerable number of cases. The average age on admission was found to be approximately $6\frac{1}{2}$ weeks, and the average age at which the first symptom occurred was 3 weeks. These figures apply to the total series; males and females, since it is impracticable to attempt a separate analysis of male and female cases owing to the very small number of the latter.

Place in Family

The following table shows the place in family of the cases in this series. It will be noted that more than half were first children, and a further 28 per cent. were from second and third pregnancies. No evidence was forthcoming of the occurrence of more than one case in a family.

Place in Family	Cases	Percentage
1st	77	56.8
2nd	23	16.9
3rd	15	11.0
4th	6	4.4
5th	7	5.1
6th	3	2.2
7th	2	1.5
8th	1	0.7
9th	2	1.5
No record	9	

Although this table suggests that congenital pyloric stenosis is an abnormality which has a peculiar selective incidence for the first-born, it is necessary before drawing any such conclusion to have controls with which to compare these figures, since it must not be forgotten that in the general population there is a much higher proportion of first-born children than, for example, fifth- or sixth-born. It is possible, therefore, that the preponderance of first children in this series is merely apparent and not real. For the purpose of control, the place in family of 150 infants admitted to the hospital for various complaints, other than congenital pyloric stenosis, was ascer-

GRAPH 1.—Showing age on admission and age at first symptom for the total cases.

the general population show that the proportion of male to female births in Scotland is 1.02 to 1. This striking preponderance of males, which is so universally recog-

tained, and the age and sex incidence of this control group was approximately the same as for the pyloric stenosis cases. The following table shows the place in family of the 150 control cases.

Place in Family	Cases	Percentage
1st	31	20.6
2nd	36	24.0
3rd	17	11.3
4th	18	12.0
5th	17	11.3
6th	9	6.0
7th	6	4.0
8th	6	4.0
9th	2	1.3
10th	3	2.0

As a further control 230 records of newborn infants, supplied to us by Dr. T. Y. Finlay of the child welfare department, were examined to ascertain the place in family of each infant. The results of this investigation were as follows:

Place in Family	Cases	Percentage
1st	45	19.6
2nd	66	28.7
3rd	31	13.5
4th	30	13.1
5th	13	5.7
6th	10	4.3
7th	17	7.4
8th	6	2.6
9th	4	1.7
10th	3	1.3
11th	0	0.0
12th	1	0.4
13th	1	0.4
14th	1	0.4
15th	1	0.4
16th	1	0.4

From these tables it will be seen that the percentage of first-born infants is comparatively low when compared with the pyloric stenosis series—approximately 20 per cent. as compared with 56 per cent. The distribution of the controls shows at least one unexpected feature, inasmuch as the number of first-born was actually less than the number of second-born. This raises some suspicion of a degree of selection. We may reasonably assume, however, that with our controls as given, the first-born in the family is actually much more likely to be affected with congenital pyloric stenosis than the younger brothers and sisters.

Birth Weight and Weight on Admission

Graph 2 shows the weight at birth and the weight on admission to hospital. It will be observed that the peak of the birth weight curve occurs at $8\frac{1}{2}$ lb.; this is of interest in that it demonstrates that the majority of infants born with stenosis of the pylorus are strong and healthy at birth, and tend to be above the average birth weight. The average weight of a newborn male infant is usually considered to be about $7\frac{1}{2}$ lb.; in this series

seventy-seven out of 121, or 63.6 per cent., of those regarding whom information as to birth weight was available weighed over 8 lb. The actual average weight at birth for the total series was $8\frac{1}{2}$ lb.

With regard to the weight on admission, the peak on this curve is at $6\frac{1}{2}$ lb., the average admission weight for the whole series being 6 lb. 6 oz. Thus it will be seen that the child usually comes to operation weighing nearly 2 lb. less than it did at birth. This loss of weight is all the more striking since it occurs at a time of life when the child should be rapidly gaining weight. Out of the total cases operated on only fourteen weighed more at the time of operation than they did at birth, and the average age of these children was unusually high—namely, 9 weeks.

First Symptom and Visible Gastric Peristalsis

The two outstanding symptoms associated with pyloric stenosis are projectile vomiting and constipation, and an analysis has been made of the frequency of the occurrence of each as the first indication of pyloric obstruction. In 129 out of the total of 145 cases, or 89.7 per cent., vomiting was the first and only symptom, the constipation not being noticed until a later date. In seven cases, or 4.8 per cent., constipation was the first symptom noticed, and in the remaining nine cases, representing 6.2 per cent., vomiting and constipation were reported to have begun simultaneously. As has already been mentioned, the average age at which the first symptom appeared was 3 weeks, the range varying from birth to the age of 9 weeks.

Visible gastric peristalsis was present in 141 cases, or 97.2 per cent. of the total. Furthermore, it is probable that in the four negative cases visible peristalsis was present, but had not been evident at the time of examination. A palpable tumour in the region of the pylorus was detected in only thirty-five cases, representing

24.1 per cent. In all these, visible peristalsis was also present. From this analysis, therefore, we must conclude that a palpable tumour in the pyloric region is a comparatively infrequent sign of congenital pyloric stenosis, and reliance should always be placed on the almost constant sign of visible gastric peristalsis in coming to a positive diagnosis.

The frequency of these two signs in this series may be conveniently shown thus:

	Present	Absent
Gastric peristalsis ...	141 (97.2 per cent.)	4 (2.8 per cent.)
Pyloric tumour ...	25 (24.1 ..)	110 (75.9 ..)
Peristalsis + tumour ...	35 (24.1 ..)	110 (75.9 ..)

Operation

The following table shows the number of cases of congenital pyloric stenosis treated by operation and by non-operative procedures respectively during the last twelve years.

GRAPH 2.—Showing birth weight and admission weight of the total cases.

	1922-1928	1929-1933
Operated on	-	105
Not operated on	40	25
Total... ..	80	130

These figures demonstrate quite clearly the striking increase in popularity of operative treatment in this condition; during the years 1922 to 1928 only 50 per cent. of the admissions to hospital were subjected to operation, whereas in the later period, 1929 to 1933, 80 per cent. were operated on. Another interesting feature is the larger number of cases in the later group than in the earlier one. It will be seen that in the seven-year period 1922 to 1928 the total number of cases of pyloric stenosis admitted to hospital was only 80, as compared with a total of 130 in the shorter period 1929 to 1933. If the average yearly admissions be compared in the two groups it is found that approximately eleven cases were admitted each year between 1922 and 1928, and a yearly average of twenty-six between 1929 and 1933. Whether this increase in numbers in recent years is due to the fact that congenital pyloric stenosis is being more generally recognized, or whether the condition itself is actually occurring more frequently, it is impossible to say, but there does not appear to be any good reason to suppose that this congenital abnormality should be more frequent at the present time than it was ten years ago.

The operation performed was the simple procedure of dividing the pyloric musculature, as first advocated by Rammstedt. Rammstedt's operation has now been carried out almost as a routine measure in the hospital for a number of years, and has been found to be the simplest and most satisfactory. Whenever possible the operation is performed under local anaesthesia, and the child is given a feed while it is actually in progress.

In the present series local anaesthesia alone was employed in 111 cases, or 76.6 per cent. of the total. In seventeen cases, or 11.7 per cent., the operation was begun with local anaesthesia, but it was found necessary to supplement this with a little general anaesthesia during the handling of the stomach. In the remaining seventeen cases the operation was performed under a general anaesthetic.

Operation Mortality

In view of the almost universal adoption of operation as the most satisfactory treatment in the majority of cases of congenital pyloric stenosis some facts regarding the mortality must be given. By operation mortality we mean patients who died apparently as a direct result of operation or of some operative complication. In this series thirty-six patients died as a direct result of the operation, representing a mortality rate of 24.8 per cent. The number of days which elapsed after operation before death occurred is shown as follows:

Days	0	1	2	3	4	5	6	8	9	10	11	13	14	19	21	31	34	Total
Cases	2	4	5	1	2	1	5	2	4	2	2	1	1	1	1	1	1	35

From this it will be seen that more than half of the patients died within one week of operation, and three-fourths within ten days.

The following table shows the number of operations performed and the mortality rate for the various years. These figures suggest that there has been comparatively little reduction in the operation mortality rate during the

past ten years, although admittedly the number of cases included in the earlier group (1922 to 1928) is too small to enable accurate conclusions to be drawn regarding the success of operation.

Operation Mortality in Various Years

Years	Cases	Deaths	Mortality per cent.
1922-1923	43	11	27.5
1929	18	7	38.9
1930	22	7	31.8
1931	22	5	22.7
1932	23	3	13.0
1933	15	3	20.0
Totals ...	143	36	24.8

Cause of Death

The various causes of death were: collapse 24, or 66.6 per cent.; enteritis 9, or 25 per cent.; sepsis 2, or 5.6 per cent.; peritonitis 1, or 2.8 per cent. The "collapse" cases are of special interest in that no definite pathological abnormality could be discovered at necropsy. Most of the patients in this group appeared to survive the actual operation quite satisfactorily, but within a comparatively short time showed signs of extreme weakness and, in spite of the administration of a variety of stimulants, failed to survive. It is a true description to state that these infants simply "faded away" for no apparent reason.

In an endeavour to discover some reason for the alarming operation mortality the cases which failed to survive have been compared very closely with the others, in the hope that some feature might present itself which would give us a clue for assessing operation risk in this condition. Unfortunately we have not been able to arrive at any very definite conclusion as a result of this investigation. It was thought, possibly, that several factors might be concerned in operative risk, and it will be of interest to consider each of these separately. First of all it occurred to us that the weight of the infant at the time of operation might have some bearing on the success of the treatment—the larger and less starved the infant the better the prognosis. This, however, was found not to be the case, since the average weight at operation of those patients who failed to survive was found to be 6 lb. 4 oz., as compared with 6 lb. 10 oz. for those who survived. This slight variation cannot be regarded as significant when dealing with a comparatively small series. If we compare the birth weights and the operation weights of the survivals and non-survivals, it is found that the loss of weight has been practically the same in both groups. In the fatal cases the average loss of weight since birth was 1 lb. 13 oz., as compared with an average loss of 1 lb. 15 oz. in the survivals. These figures suggest that neither the actual weight at operation nor the rate of loss in weight since birth has any appreciable influence on the operation mortality. It must be realized, however, that when dealing with a small series such as this it is probably unwise to draw any definite conclusions from such figures.

The age at operation and the age at which the first symptom was noticed in those patients who died does not show any significant difference from the survivals, the average ages at operation being 6½ weeks and 6 weeks respectively, and the average age when the first symptom appeared being 3 weeks for both those who died and those who survived. These points of comparison between the deaths and the survivals are shown in the following table.

	Average Weight		Average Age	
	At Birth	At Operation	At First Symptom	At Operation
Survivals	8 lb. 9 oz.	6 lb. 10 oz.	3 weeks	6 weeks
Deaths ...	8 lb. 1 oz.	6 lb. 4 oz.	3 ..	61 ..

As in the case of the survivals, local anaesthesia was employed for the majority of the patients who died. Of the thirty-six operation deaths, local anaesthesia alone was used in twenty-six, general anaesthesia in six, and in the remaining four both local and general anaesthesia were required. Thus it will be seen that the type of anaesthetic cannot be blamed for the operation mortality.

From this comparison of the deaths with the survivals it must be concluded that no significant fact has arisen which enables us to predict the chances of survival in any particular case.

In addition to the thirty-six patients who died as a direct result of operation, four others died within a comparatively short time of operation from other causes. One developed diphtheria with fatal consequences six weeks after operation, and a second developed septicaemia as a result of abscesses in both axillae, which had been caused apparently by the administration of subcutaneous glucose saline. The remaining two patients were discharged from hospital in good condition, but were readmitted some weeks later with severe enteritis, from which they ultimately died. These four cases have not been included under the heading of operation mortality, since it seemed probable that the operation had little or nothing to do with death in each case.

Operative Complications

Some operative complication arose in twenty-nine cases, or 20 per cent. Post-operative enteritis accounted for nearly two-thirds of the total complications, and as a result death occurred in nine cases. The frequency of the various complications was: enteritis, seventeen; severe vomiting, six; sepsis, three; bronchitis, two; acute parotitis, one.

The six cases under the heading of severe vomiting are mentioned on account of the severity of the symptom, since in each it was found necessary to substitute parenteral feeding for several days following operation, the patients being unable to retain anything in the stomach. One of these died. A number of patients suffered from occasional slight vomiting after operation, but these are not included under operative complications.

Length of Stay in Hospital

The length of stay in hospital of the patients in this series is shown in the following table.

Weeks	0-1	1-2	2-3	3-4	4-5	5-6	6-7	Over 7	Total
Cases ...	6	31	17	16	9	9	7	12	106

In this table only those patients who survived operation are included, as the length of stay in hospital of those who died has already been discussed. It will be noted that fifty-three patients were discharged within three weeks of admission; this represents 50 per cent. of the total. The patients who remained a longer time were those who had received preliminary treatment in the medical wards prior to operation, or who developed post-operative complications necessitating detention in hospital for long periods. The six patients who remained for less than one week are of interest in that they were treated as out-

patients, and after remaining under observation for a few hours following operation were allowed to go home, with instructions to report progress from time to time. The result in these cases was highly satisfactory. When the lengthy stay in hospital required for the medical or non-operative treatment of congenital pyloric stenosis is considered it must be admitted that on this score, at any rate, the operative treatment of the condition has a very definite advantage over the medical.

Comparison of Early with Later Group

An attempt has been made to determine whether congenital pyloric stenosis is being diagnosed more readily to-day than it was a number of years ago. For this purpose we have divided the cases in this series into two groups. Group 1: cases which were operated on during the period 1922 to 1929, fifty-eight cases. Group 2: cases treated during the period 1930 to 1933 inclusive, eighty-seven. In each group the average age at first symptom and on admission to hospital has been estimated, in order to note the length of time which elapsed between the first manifestations of the disease and the date when the patients were actually referred to hospital for treatment. The figures are shown in the following table.

	Group 1	Group 2
Average age { First symptom ...	2.7 weeks	3.0 weeks
{ Admission ...	6.4 ..	6.9 ..
Difference ...	3.7 ..	3.9 weeks

This table reveals that there is no significant difference between the early and later groups of cases; we must conclude, therefore, that the possibility of the presence of congenital pyloric stenosis in a vomiting baby is not being considered any more to-day than it was five to ten years ago.

Commentary

The most striking and disquieting feature which is revealed by this investigation is the high operative mortality rate, as it will be seen that approximately one patient out of every four operated upon for this condition may be expected to die as a result of the operation. As has been shown there is no unusual feature characterizing those infants who fail to survive operation. Furthermore, the majority who died did not suffer from any recognized post-operative complication, nor was any satisfactory explanation of death discovered post mortem. We must conclude, therefore, that nearly 25 per cent. of infants who come to operation for congenital pyloric stenosis are in such a weak state that they are unable to survive even the comparatively minor operative procedure which is adopted. In this series the operation was carried out with a minimum of disturbance to the infants. Local anaesthesia was employed in a high proportion of cases, and the majority of infants during the operation did not show any signs of distress, so that it may be fairly claimed that post-operative shock was reduced to a minimum.

It would seem, therefore, that if good results are to be obtained in the treatment of congenital pyloric stenosis, and if the operation mortality is to be reduced to a reasonable figure, it is essential that the condition should be diagnosed and treated at a much earlier date than it is at present. In so many cases we find that for a period of three to four weeks after the commencement of symptoms these infants are considered to be suffering merely from dyspepsia, and the feeding is changed every few days in the vain hope that the vomiting will cease.

Eventually, when the child is more or less *in extremis*, it is sent to hospital in a state of health which makes any form of treatment a dangerous procedure.

We would suggest that pyloric stenosis in infancy should be regarded far more than it is at present as an abdominal emergency, and it should be realized that the longer the delay in sending the child for treatment the less are its chances of survival. Admittedly, vomiting in infancy is a frequent occurrence, and is due, in the majority of cases, merely to some feeding defect or mismanagement; nevertheless, we believe that until congenital pyloric stenosis is considered as a possibility in every case of forceful vomiting in infancy the mortality from every form of treatment must remain at a high level. It is probable that if the condition were diagnosed within one week of the commencement of symptoms and sent for operation without delay, as in other cases of abdominal emergency, the operation mortality would be greatly reduced.

Summary

An analysis has been carried out of 145 cases of congenital hypertrophic stenosis of the pylorus treated by operation. The proportion of males to females in this series was 6.25 to 1. More than half of the patients were first children, and it is revealed that the last child in a large family very rarely suffers from this condition. This analysis shows that the birth weights of the infants concerned were somewhat higher than the normal average for males. The average weight at birth for all the cases in this series was 8½ lb.

The first symptom noticed in the majority of cases was vomiting, and the average age at which it occurred was three weeks. Visible gastric peristalsis was an almost constant sign, whereas a palpable tumour in the pyloric region was noted in only 24 per cent. before operation. The operation mortality was 24.8 per cent., and there is no indication of any marked fall in mortality during the last ten years. The patients who failed to survive did not appear to differ significantly at the time of operation from the survivors, and in a high proportion of deaths no adequate cause could be discovered at necropsy.

The time that elapses between the first manifestation of obstruction and the admission of the patient to hospital for treatment is between three and four weeks, and there is no evidence to show that pyloric stenosis in infancy is being recognized any earlier to-day than it was ten years ago.

We wish to record our thanks to the physicians and surgeons of the Royal Edinburgh Hospital for Sick Children, who have kindly placed their case records at our disposal. We also gratefully acknowledge the help of Colonel Harvey and Dr. Kermack of the Royal College of Physicians Laboratory for advice and criticism in the preparation of this paper.

Commemoration Day at Livingstone College, Leyton, was held on June 14th, when General E. J. Higgins of the Salvation Army presided over a large gathering and congratulated the principal, Dr. Tom Jays, and the college generally on the success of their work in providing training in medical subjects for missionaries. "I did not come here," he said in conclusion, "to appeal for funds, but the burdens of finance are pressing. We cannot all go to the mission field, we cannot all come to Livingstone College (most of us are too old), but there are lots of other things we can do, and I feel we could free the college from the burdens that are upon it through lack of money." The Rev. G. Harp of the Moravian Mission, Labrador, said that the year's training he received at Livingstone College had been very useful indeed, and he was most thankful for the help he had received. Dr. Jays said that this year they had had thirty-two students, seventeen of whom were at the college for the whole session. They depended very largely on students' fees to pay their way, and last year there was a deficit of £650.

AN IMPROVED METHOD FOR THE DETERMINATION OF BILIRUBIN IN BLOOD

BY

PROFESSOR A. A. HIJMAN VAN DEN BERGH, M.D.

AND

W. GROTEPASS, M.D.

(From the Medical University Clinic, Utrecht, Holland)

Considerable inaccuracies are inherent in the test for bilirubin in the blood serum as an azo-derivative. We have always preferred, therefore, to call it a quantitative estimate¹ rather than a quantitative determination. The method, however, which owes its widespread use largely to McNee's investigations, continues to be employed chiefly because no better test has yet been found. One of the errors of the method is due to the adsorption of a varying quantity of pigment to the albuminous precipitate during the performance of the test. This objection has been partly circumvented by Thannhauser's modification.² A second error, which must not be neglected, appears in the colorimetric comparison of the azo-bilirubin solution with a standard solution. Our attention was especially devoted to this second error when we critically reconsidered the method. To use as a standard a solution of artificial bilirubin which has to be freshly made for every test is almost impracticable for several reasons. The cobalt sulphate solution we recommended differs considerably in colour-tone from the azo-bilirubin solution, and this makes an exact colorimetric comparison very difficult.* The ethereal solution of rhodanate of iron formerly suggested matches the azo-bilirubin slightly better in colour. The great and rapid change in concentration of an ethereal solution, however, is a serious drawback. A solution of potassium permanganate has been advocated, and this really gives colours which are better matched, but it provides no complete similarity. A permanganate solution, moreover, has the drawback of soon losing its concentration when the solution is weak, and this renders it necessary to make a fresh solution of the desired strength fairly often, thus diminishing the practicability of the method as a routine test. In order to circumvent these difficulties we resorted to carrying out the test in monochromatic light, avoiding in this way the difference in colour between the fluid for comparison and the fluid to be examined—a very disturbing difference in "white" light. This procedure really changes the colorimetry, which is the comparison of the intensity of two colours, into a photometry in monochromatic light, which is a comparison of two strengths of a qualitatively similar light.

Instrumental Modifications

Several more or less costly instruments constructed according to this principle have been recommended. We have used, with good results, one of the ordinary colorimeters common in many laboratories, and have covered the eye-piece with a light-filter. We chose Klett's colorimeter, the new model, in which the source of light is in the foot of the instrument. Schott's green light-filter (S. 52), which only transmits rays of 520 to 546 $m\mu$, was placed on the eye-piece. At first we employed the cobalt sulphate solution, originally described as our standard

* The concentration of the cobalt sulphate solution appears to be 2.15 per cent., and not 2 per cent., as we indicated in our publication *Der Gallenfarbstoff im Blute* (McNee, *British Medical Journal*, 1923, ii, 52). This difference from our former quotation is probably due to a mathematical error on page 17 of the above-mentioned publication, where the azo-bilirubin concentration is mentioned as being 1 in 250,000, and not 1 in 200,000 (cf. Habinowitch, *J. M. Jour. Biol. Chem.*, 1922, xcvi, 163).

solution. The errors in reading were very slight (less than 2 per cent.) by this technique, which far surpasses the results of colorimetry in unfiltered light. The technique, however, can still be improved. The fluids, for comparison always provide difficulties for the routine test, especially in clinical laboratories. The preparation of the standard solutions takes time, and chemical analysis is often necessary to test possible changes of composition.

Non-fluid Colour Standards

It is a great advantage to be able to dispense with a fluid for comparison, and the possibilities of this proposition are easily recognizable. The filtered light sent out by the source of light can easily be dimmed in another way and not by the interposition of a pigment solution as a standard for comparison. Vierordt's spectrophotometer, the Stufenphotometer, and Leitz's absolute colorimeter are a few of the instruments that are constructed in accordance with this principle. We have tried a few aids to dimming the light which differ from the above-mentioned instruments. First we interposed a smoked glass, and this gave very good results. In this method one of the vessels of Klett's colorimeter is filled with the azo-bilirubin solution to be examined; the other vessel either remains empty, or, preferably, is filled with the corresponding solving fluid, and is fixed at a constant height. The smoked glass is placed on the ring that supports the latter vessel. The vessel filled with azo-bilirubin solution is brought into the position in which the colours are similar. The standard vessel is filled with a solution of pure bilirubin, and from this azo-bilirubin is made by a technique which we will describe later in this paper. Several solutions of different strength (in 70 per cent. alcohol) are made of this azo-bilirubin, and a standard curve is deduced from them.

We have, however, now abandoned this smoked glass method, because technical experts feared that the action of these glasses might gradually change. The dimming effect of smoked glass, moreover, is not the same for all regions of the spectrum. Thus errors might occur if the described technique were employed for the colorimetry of other fluids. We rejected an experimental instrument with crossed Nicol prisms for several reasons, and tried an even simpler method of dimming. Instead of the smoked glass we took a metal diaphragm painted black, with a small hole in the centre. The results thus obtained were inferior to those of the smoked glass method. What are the physical causes for the slight changes in colour thus effected we have not been able definitely to ascertain: it is possible that diffraction phenomena might be important. We then replaced the diaphragm with its central hole by a small wire gauze painted a dull black. The wires had a diameter of 0.35 mm., and the meshes measure 1 mm. A gauze of this nature enables us, as is well known,² to dim the light to a desired proportion. The gauze has the great advantage over the smoked glass in that it dims the light equally in all wave-lengths, and is thus suitable for the examination of all colours. It is, moreover, exceptionally simple and cheap. Messrs. Kipp and Sons (Delft, Holland) are constructing a practical apparatus for quantitative determination of coloured solutions without standards after those principles.

The pH of Fluids in the Direct Reaction

A new difficulty was encountered when we endeavoured to apply this method to the determination of the bilirubin content of the blood serum with the direct reaction. At first the test was performed in the following manner: a certain amount of the reagent was added to the serum

and thereafter a certain amount of alcohol (96 per cent.) and saturated ammonium sulphate. It was then found that, after centrifugalization, a fine turbidity gradually appeared in the red solution, which had been at first clear. This turbidity was, of course, a source of error by dimming the in-coming light in the photometer. A remark of Professor Kruyt's (Utrecht) made us investigate whether the use of less concentrated alcohol might prevent the formation of this albuminous precipitate. We found, after some experiment, that if 50 per cent. alcohol was added there was no vestige of turbidity even after several hours (up to twenty-four) when the correct proportions of alcohol, serum, and reagent were also employed. This method completely abolished at the same time the error mentioned at the beginning of this paper, and which Thannhauser had already tried to circumvent—the loss of bilirubin by adsorption to an albuminous precipitate. When this difficulty had been overcome a new question arose. It appeared that the azo-bilirubin solutions, obtained respectively from chemically pure bilirubin, from bilirubin in serum with a direct reaction, and from serum with an indirect reaction, did not completely match in colour-tone. That the difference in the pH of the fluids was the cause of this phenomenon was proved by subsequent investigation, and the addition of a buffer to the fluids made it possible to obtain nearly perfect similarity of tint. Mellvaine's buffer was found to be most suitable. It consists of 27.25 c.cm. of 0.1 mol. citric acid, and 72.75 c.cm. of 0.2 mol. secondary-sodium phosphate (Sørensen). The pH of the solution is 6.6.

In order to prove even more exactly the similarity in tint, absorption curves of the three different solutions (see diagram) have been measured in the laboratory of

Professor L. K. Wolff, in association with his collaborator Dr. Josephy, by means of Hilger's large spectral instrument. The shape of the curve shows that the light absorption of the three solutions is practically identical in the region of maximal extinction.

It may, we think, be concluded with the greatest possible certainty that the quantity of bilirubin contained in a serum can be estimated by comparing the light absorption of its azo-compound with the light absorption caused by the azo-compound of an artificial bilirubin solution in the spectral region of the maximal light-absorption, which is between 520 and 546 μ .

We have now discussed our reasons for the proposed change in our original method for the quantitative determination of bilirubin, and the investigations which led to it: the technique of the test will now be more accurately described.

Special Techniques

The Reaction with Artificial Bilirubin

A small vessel is filled with a freshly made solution of azo-bilirubin. To this end 5 mg. bilirubin is dissolved in 100 c.cm. chloroform; 10 c.cm. of this solution is evaporated under CO_2 in a water-bath until it is nearly dry. About 60 c.cm. of a fluid consisting of 50 per cent. alcohol which contains 10 c.cm. of the above-mentioned buffer solution of pH 6.6 to every 100 c.cm. is added to the residue. The buffer alcohol is heated for some time in order to evaporate the chloroform. Next, the fluid is brought to room temperature, and to it is added 20 c.cm. of the reagent, consisting of (A) 1 gram sulphanilic acid, 15 c.cm. of 25 per cent. HCl, with distilled water up to 1 litre; and (B) 0.5 per cent. sodium nitrite in aqueous solution.

Ten c.cm. of Solution A is mixed with 0.3 c.cm. of Solution B shortly before use. The buffer containing alcohol is added to the fluid after the reagent, and the total quantity is brought up to 100 c.cm. The pigment solution which is to be examined must be left in the dark for fifteen minutes in order to complete the "coupling." Several solutions, all differing by 5 per cent., are made from the azo-bilirubin which has thus been obtained. In this way the weakest solution has half the strength of the original solution, and thus equals 1 in 400,000 bilirubin. One of the vessels is now filled in turn with these different solutions, and the height is determined to which it must be raised in order to obtain a similar light intensity to the other half of the field of vision. The readings of the numbers are marked on the ordinates of a millimeter paper scale and the corresponding units of bilirubin are marked on the abscissae. This constitutes the standard curve of the instrument.

The Direct Reaction

Two c.cm. reagent is added to 1 c.cm. serum. The solution is left in the dark for five minutes, 2 c.cm. of water is added, and then the alcoholic buffer solution up to 10 c.cm. The "coupling" is complete after fifteen minutes. This method keeps the solution perfectly clear for several hours, and a slight turbidity appears only after twenty-four hours. If the serum contains a great amount of bilirubin, and if the azo-solution has, in consequence, a very bright colour, then it must be diluted as often as necessary with 25 per cent. buffer alcohol.

The Indirect Reaction

Two c.cm. serum is mixed with 4 c.cm. alcohol (96 per cent.) and centrifuged. The clear supernatant fluid is placed in a test tube. Four c.cm. of this solution is placed in a second test tube, and 0.5 c.cm. reagent and 1 c.cm. alcohol are added to it. Wait one or two minutes to obtain maximal colour before using the colorimeter. The dilution factor is 4.

$$\frac{20}{7} \times \frac{5.5}{4} = \frac{5 \times 5.5}{7} = \frac{27.5}{7} = 4 \text{ approx.}$$

It has not been possible to improve this reaction, apart from also employing the filtered (green) light for quantitative determination. We do not commit a grave error by adhering to our original technique in this case, as the quantity of pigment adsorbed to the albuminous precipitate is small in these circumstances.

In these investigations we initially used different proprietary preparations for making the necessary bilirubin solutions. These, however, did not all give, in solutions of the same strength, a quantitatively similar light absorption after diazotizing. We have therefore standardized our instrument with chemically pure bilirubin, with which Professor H. Fischer (Munich) has kindly provided us. An examination of different preparations with the standardized instrument showed that the bilirubin preparations of Hoffman La Roche (Basel) and Fraenkel Landau (Berlin) are exactly similar to Professor H. Fischer's pure preparation.

Summary

This paper describes an improved technique for the determination of bilirubin in the serum by means of the diazo method.

The first improvement is the colorimetric determination in monochromatic light by means of a dimming wire

gauze, instead of the fluid for comparison which was formerly used. This instrument is standardized with azo-bilirubin, derived from chemically pure bilirubin.

The second improvement is the prevention of the adsorption of bilirubin to the albuminous precipitate which occurred when the old technique was followed. This result is achieved by adding, in suitable proportions to the serum, a mixture of reagent, diluted alcohol, and a buffer.

THE ANTE-NATAL USE OF QUININE

BY

F. W. BUDDEE, M.B., CH.M.(SYD.), M.C.O.G.

LATE RESIDENT MEDICAL OFFICER, QUEEN CHARLOTTE'S HOSPITAL

Several references to the advantage of giving quinine in small doses in the last few weeks of pregnancy have appeared from time to time in the journals. Mitchell¹ (1930) was enthusiastic, and Gair Johnston, Hewetson, and Green-Armytage wrote letters to the *British Medical Journal* on the subject in August, 1933. Special attention was called to the easy labour of the malarial patient under treatment with quinine.

This paper deals with a series of one hundred cases—sixty-six primiparae and thirty-four multiparae—who have been given quinine hydrochloride during the last weeks of gestation. For comparison, a series of the same number of primiparae and multiparae has been taken; in each series toxæmias in any form, and gross pelvic contraction, have been excluded, but otherwise the cases have been selected from the ante-natal booked patients of Queen Charlotte's Hospital.

Pharmacology

Quinine has long been credited with oxytocic properties. It has a direct action on involuntary muscle; in weak concentration it stimulates contraction, but in strong concentration it depresses (Sollman)²; its action is most marked on the uterine muscle, but in animals the intestinal muscle is also effected and splenic contraction also occurs. In the human uterus in labour, however, Bourne and Burn³ showed it had very little effect in hastening delivery, for while it increased the frequency of contractions they were not as powerful. Numerous workers have agreed that it is of no value in the induction of labour except in fully mature or post-mature cases, and medical inductions with quinine and pituitrin have given the same percentage of success when the quinine has been omitted. Quinine has also general tonic properties. It is a general protoplasmic stimulant in small doses, but this is only a transitory augmentation of activity, and in larger doses it is a protoplasmic poison (Cushny).⁴ Its tonic and stomachic action is well known, while its antipyretic properties and specific action in malaria need no mention here. With regard to its increasing resistance, it causes first a mild leucocytosis (followed soon afterwards by a leucopenia) and in higher concentrations it is detrimental to phagocytosis and agglutination (Cushny).⁴

The drug is excreted by the kidneys, but the greater proportion absorbed is destroyed in the body (60-70 per cent.). It appears in the urine fifteen to twenty minutes after ingestion, and the greatest concentration independent of the dosage is present in six to ten hours, though small quantities may be found in the urine for twenty-four to forty-eight hours. It reaches the foetus through the placenta, and has been recovered from foetal urine, liquor amnii, and placental tissue (Dilling and Gemmell).⁵ Excretion by the foetus is thought to be slow, and concentrations of 1 in 100,000 are likely to cause intrauterine death.

Small doses cause marked disturbance in some people (quinism), usually in the nature of disturbance of hearing

and sight, mental confusion, and depression. Skin eruption is perhaps the commonest manifestation of idiosyncrasy, and a large variety of scarlatinal and urticarial rashes have been described (Sollman and Cushny).

Torland described a severe rash associated with foetal death. A possible test for idiosyncrasy is the application of a strong solution of quinine to the scarified skin. In one of the cases given quinine a severe erythematous rash developed after three doses of 5 grains (taken each night) and premature labour followed, but not foetal death (Case 1). One baby developed a mild rash after twenty-four hours, which may have been caused by quinine. In two patients also the quinine had to be discontinued on account of sickness and headache, in one after six and in another fourteen days. Three cases felt sick for the first three doses, but then continued without further trouble. In this series there was therefore a 3 per cent. idiosyncrasy to the drug.

Dosage and Duration of Medication

The aim in this series was to commence quinine at about the thirty-sixth week of gestation, and to continue until the onset of labour. Quinine hydrochloride in 5-grain tablets was given at night in each case. Labour commenced at varying times—after three days in one case and after fifty-four days in the longest of the series.

The following table shows approximately the number of doses of quinine given.

Onset of Labour

Under 7 Days	7-14 Days	14-21 Days	21-28 Days	28-35 Days	35-42 Days	42-56 Days
4	12	18	23	17	18	8

There appeared to be no relation between the number of doses and the duration of labour. With regard to the period of gestation at which labour commenced fewer cases of the quinine series went past the fortieth week of gestation calculated in the usual method from the last menstrual period.

The following table shows a comparison of the quinine and control series.

Week at which Labour Commenced	35th	37th	38th	39th	40th	41st	42nd	43rd
Quinine { Primiparae ...	1	4	8	15	29	7	1	1
Quinine { Multiparae ...	2	1	8	4	15	2	1	1
Control { Primiparae ...	—	3	8	10	24	11	8	2
Control { Multiparae ...	1	2	4	6	13	3	3	2

Ante-natal Results

Except for the five cases already mentioned as suffering through idiosyncrasy, all cases felt and looked well. No nausea was experienced with the tablets. In quite a number muscle tone was so good that abdominal palpation was difficult, and in a small proportion the uterus appeared more irritable than normal. The incidence of premature labour was not very different from that in the control series, but in Case 1 it seemed responsible for the onset of labour.

Foetal and Neo-natal Morbidity

One stillbirth and two infant deaths occurred in the quinine series. In the stillbirth the case was one of prolonged labour, with inertia, slow dilatation, and the early passage of meconium. The foetal heart was not heard after sixty hours' labour; I do not think quinine can be held responsible. The infant deaths were due in one case to marasmus (on the fourteenth day, a full-term child, weighing 5 lb. 7 oz. at birth, which steadily lost weight),

and in the other following an operation for sacrococcygeal tumour. The control series contained three stillbirths from prolonged labours, and one infant death from bronchopneumonia.

Dilling and Gemmell, in their investigations on quinine for induction, found a high incidence of the early passage of meconium (34.8 per cent. compared with 8 per cent. in normal cases). This was not noticed in the present series, and there was no difference in the progress of the children after birth. While King and Dilling and Gemmell have each considered the higher concentrations injurious to the foetus, although not necessarily increasing the still-birth rate, I do not think in the smaller dosage continued over several weeks there is any evidence to suggest foetal distress, even where idiosyncrasy has been observed. The smallest child in the series weighed 5 lb. 5 oz. and the largest was 9 lb. 6 oz., with an average for all cases of 7 lb. 1 oz.

Uterine Contraction and Duration of Labour

Clinically, where quinine had been given the contractions appeared to be frequent and of good quality, and progress was good in most cases; the labour ward sisters considered the cases had benefited from the medication. On estimating the hours of labour in comparison with the control series, however, the results were disappointing, and very little, if any, benefit was observed, while in addition several bad cases of inertia occurred in the quinine series.

The time of onset of labour in the following tables has been estimated from when the patient first felt painful contractions of any sort, and not, as in Mitchell's series, from "when the patient has to stand still and hold a chair with each pain."

The second stage, while difficult to estimate accurately, is calculated from the routine figures on the labour ward sheets in each case.

Total Duration of Labour

	Primiparae		Multiparae	
	Quinine	Control	Quinine	Control
Under 5 hours ...	1	2	14	14
5 to 10 hours ...	11	8	12	12
10 to 18 hours ...	25	26	5	5
18 to 24 hours ...	5	9	1	2
24 to 36 hours ...	11	9	1	1
36 to 48 hours ...	1	4	—	—
48 hours and over	9	8	1	—

Duration of Second Stage

	Primiparae		Multiparae	
	Quinine	Control	Quinine	Control
Under 1 hour ...	28	32	33	32
1 to 1½ hours ...	10	15	1	1
1½ to 2 hours ...	12	5	—	1
2 hours and over ...	13	14	—	—

In both series of cases twenty-one primiparae had labours exceeding twenty-four hours. In the quinine series six of these cases were typical examples of primary inertia, with labours extending over forty-eight hours. The longest case was 101 hours for the first stage—an occipito-posterior presentation with pains of poor quality (Case 2); four others were occipito-posterior, while one

of the six was occipito-anterior with pains of just poor quality. Four of these inertias were delivered with forceps. The remainder of the labours exceeding twenty-four hours included one extended breech and twelve occipito-posterior presentations. In the multiparae one case which had inertia with her first baby had a labour of fifty-five hours, with weak, ineffective pains (Case 3).

Forceps Incidence, Caesarean Section, and Post-partum Loss, etc.

Eight cases in the quinine series had forceps deliveries, and of these, seven were occipito-posteriors needing manual rotation. In the control series two cases of occipito-posterior were delivered normally after manual rotation, and eight cases were delivered by forceps. Caesarean section was performed in three instances for disproportion. Two of these cases were interesting, in that drug induction with pituitrin was first tried and repeated in twenty-four hours at the fortieth week of gestation with the idea of a trial labour (Cases 4 and 5). The uterine muscle was apparently not more responsive to pituitrin after the quinine medication.

No excessive loss occurred post partum in either series of cases, but the numbers are too small to be of any significance. One multipara, however, who had had a retained placenta with her previous pregnancy, had a perfectly normal third stage. Retraction of the uterus was also satisfactory. Mitchell thought this an important factor in reduction of sepsis, but to consider quinine responsible for this is not justifiable, as retraction was quite satisfactory in the control series. Infection in these cases was never of any serious consequence; no haemolytic streptococci were cultured in any case. One multipara who had had quinine, however, died of pulmonary embolism on the thirtieth day. Femoral thrombosis was present, but no evidence of infection or laceration of the genital tract was seen at any stage (Case 6).

Illustrative Case Records

Case 1.—A. S., aged 36 years, a second multipara, was given quinine at the thirty-sixth week. After the second dose (5 grains each night) she had headache and nausea, and after the third dose had by morning developed an extensive erythematous rash, which was a little itchy, and mild ear and eye symptoms. By evening labour had commenced, and she was admitted to hospital with the head on the perineum after two hours of pains. Normal delivery of a living child (5 lb. 13 oz.) followed. Mother and child progressed satisfactorily, the rash disappearing after three days.

Case 2.—A. W., aged 25 years, a primipara, had quinine for forty-six days previous to labour, which did not commence until three weeks after the estimated date. She was an occipito-posterior presentation, with poor, ineffective pains, and early rupture of membranes. Dilatation of the cervix was slow, and after 101 hours an anterior lip could be pushed up; manual rotation was performed and delivery with forceps. The child's condition was satisfactory, and it weighed 7 lb. 14 oz. This case developed an acute sacro-iliac subluxation, which was treated by manipulation and plaster, with good result.

Case 3.—M. N., aged 25 years, a second multipara, had quinine for fourteen days previous to labour. Weak, ineffective pains and backache were present for forty-eight hours, but then improved, and further progress was good. The labour lasted fifty-five hours in all, and the child weighed 5 lb. 10 oz.

Case 4.—N. D., aged 21, a primipara, had quinine for forty-three days before Caesarean section for disproportion. At the fortieth week of gestation (after thirty-four doses of quinine), medical induction with oil bath enema and six doses of two units of pituitrin at hourly intervals was tried, and repeated after twenty-four hours without any result. The convalescence after the operation was normal, and the child weighed 8 lb.

Case 5.—E. P., aged 23, a primipara, was similar to Case 4. Quinine was given for twenty-eight days, and then medical induction was tried and repeated without result. The child weighed 9 lb. 6 oz.

Case 6.—D. H., aged 28, a second multipara, had quinine for twelve days before labour commenced. She was admitted to hospital with the head on the perineum, and normal delivery followed. The total duration of labour was one hour thirty-five minutes, and the child's weight 7 lb. On the evening of the third day she had a small pulmonary embolism; this recurred twice in the next two weeks, and on the thirtieth day she had a large embolism, causing death. At necropsy there was no evidence of infection or laceration in the genital tract; the left femoral vein was thrombosed, and several emboli were present in the lungs.

Conclusions

Quinine, given in small doses in the last weeks of gestation, acts as a general tonic and stimulant, and the patients feel well and are often improved. Idiosyncrasy is likely in a small percentage of cases, and its manifestations may include skin reaction and the onset of premature labour. There is no evidence to suggest any foetal toxicity or increase in foetal mortality, and, apart from idiosyncrasy, little risk of premature labour. The effect of the drug on the duration of labour is of doubtful value. Clinically, the pains appeared to be improved, but in comparison with the control series no significant difference was evident. Inertia is certainly not eliminated. The general tonic effect may have some beneficial results in reducing the liability to infection through increased resistance.

My thanks are due to the Queen Charlotte's Hospital honorary medical staff for their assistance and advice, and to the Sisters of the hospital for their aid in compiling these results.

Further information has now been received about the post-graduate course and tour in Switzerland from August 15th to 23rd, previous notification of which appeared in the *Journal* of April 21st. The Basel Medical Association will entertain members of the course on the evening of August 15th, and on the following morning there will be a lecture at the Basel municipal hospital and a visit to the new maternity hospital. The same evening there will be an official dinner at Zürich, with lectures on the new hospital buildings there. The morning of August 17th will be devoted to a visit to the Neumünster hospital, the psychiatric clinic, and the children's hospital. In the evening, at Zürich, there will be an informal welcome by the medical associations of Lucerne, and the following morning will be spent in study of the reconstructed and enlarged cantonal hospital and two local clinics. The official post-graduate course will open at Bern on the morning of August 19th with lectures on the general aspects of hospital treatment, and further lectures on cognate subjects will follow at the University on the three next mornings, with discussions. The formal course will conclude at Leysin on August 23rd, and the five following days will be spent in visits to Arosa, Davos, and St. Moritz. The whole course is arranged in three sections—namely, Basel and Lucerne, Bern and Leysin, and the Canton Grisons tour, the respective fees being 90, 150, and 150 Swiss francs. Tickets should be booked before July 1st. Further details are obtainable from the secretary of the post-graduate course, Obergrundstrasse 13, Lucerne.

OBSERVATIONS ON THE ASSOCIATION
OF HAEMOLYTIC STREPTOCOCCAL
INFECTION WITH ACUTE
RHEUMATISM

BY

WILLIAM A. R. THOMSON, M.D.

SURGEON LIEUTENANT R.N.

FORMERLY DAVIDSON RESEARCH FELLOW IN APPLIED BACTERIOLOGY,
EDINBURGH UNIVERSITY(From the Departments of Medicine and Bacteriology, University
of Edinburgh)

Since Haig-Brown¹ described the occurrence of cases of acute rheumatism in association with an epidemic of tonsillitis among the boys of Charterhouse much epidemiological evidence has accumulated in favour of the association of acute rheumatism with haemolytic streptococcal infections. Longstaff² had already shown from a study of the Registrar-General's returns that there was a close association between the incidence curves of puerperal fever, scarlet fever, and acute rheumatism, while Dudley,³ in a study of the association of acute rheumatism with outbreaks of tonsillitis due to the haemolytic streptococcus among the boys on board the training establishment *Impregnable*, has shown that the annual attack rates per 1,000 were 397 for tonsillitis and 43.7 for rheumatic fever. Glover and Griffith⁴ have reported similar outbreaks in public schools where, as in the case of the training ship, sleeping arrangements were ideal for the transmission of droplet infections. A full study of this aspect of the question is to be found in Glover's Milroy Lectures (1930).⁵

Interest in this association of the haemolytic streptococcus with acute rheumatism has been enhanced of late by the work of Coburn in New York and Collis, Sheldon, and Schlesinger in London. Coburn⁶ showed that when children suffering from rheumatic fever were removed from New York to Porto Rico, not only was the haemolytic streptococcus persistently absent from swabs of the throat, but rheumatic relapses were unknown, and the children made uninterrupted recoveries. When the children returned to New York, however, haemolytic streptococci reappeared in the throat, and several rheumatic relapses occurred. Collis⁸ and Sheldon⁹ reported an epidemic of rheumatic relapses in a convalescent hospital for rheumatic children. Here the relapses were all preceded by tonsillar infections due to the haemolytic streptococcus. Further attention has been drawn to the subject by the work of Todd,¹⁰ who has demonstrated the presence of a high titre of "anti-haemolysin" in the blood of patients suffering or convalescent from acute rheumatism.

Four Cases Encountered in Edinburgh

During an investigation into the aetiology of acute rheumatism that is at present being carried out in Edinburgh, four cases have been encountered which illustrate this association, and which, in view of its importance in relation to the aetiology of acute rheumatism, are now reported.

CASE I

A girl, aged 3 years 9 months, was admitted to the Royal Hospital for Sick Children, Edinburgh, on March 29th, 1932, with a history of weakness and twitching of the right arm and leg for one week. There was no history of headache, strabismus, delirium, or coma, and no family history of rheumatism. The only points of note were that she had had intermittent attacks of pain in the right ear since infancy, and four weeks before admission she had had a "slight cold." On admission she was a well-proportioned, well-nourished child, of average intelligence, but very emotional.

There were marked choreic movements of the face, eyes, and all four limbs, more emphasized on the right side. Speech was considerably impaired, and she was unable to feed herself; both tonsils were slightly enlarged. Nothing abnormal was detected about the heart. The urine contained albumin, and, microscopically, a few red blood cells, but no casts. The following are notes on the progress of the case.

March 31st: Antipyrine, 5 grains three times a day. April 5th: Patient feeding herself; still considerable ataxia. April 11th: Faint, discrete, erythematous, and irritating rash on trunk, antipyrine rash; antipyrine stopped. April 13th: Temperature 100.2°; widespread erythematous rash affecting trunk, lower extremities, and upper extremities to lesser extent—closely set, bright red spots, fading on pressure, not quite so fine as typical scarlatiniform rash; face flushed; no sore throat. April 14th: Rash rapidly fading. April 19th: Well-marked "peeling" of the face. April 30th: Patient active and cheerful, with no noticeable ataxia; had lost 10 lb. in weight since the 14th; had also had impetigo, which responded to routine treatment.

May 1st: Temperature 102°, pulse 140; tonsils congested; high-pitched, blowing systolic murmur audible in the mitral area; sodium salicylate, 10 grains three times a day. May 2nd: Temperature 101.2°, pulse 132; systolic murmur more intense. May 3rd: Temperature 101.2°, pulse 136; haemolytic streptococci isolated from throat swab; reduplication of second sound in pulmonary area; sodium salicylate stopped. May 5th: Skin reaction to intradermal injection of extract of haemolytic streptococci positive; Dick reaction negative; haematuria present. May 7th: Haematuria diminishing; face puffy. May 9th: Preceding night restless; patient very breathless; at 6 p.m. she had an attack of vomiting, followed by cyanosis and a period of intense dyspnoea; during this attack the heart sounds were tumultuous and entirely masked by murmurs. May 10th: Temperature 100°, pulse 148; patient still breathless; apex beat in the sixth intercostal space, just external to the midclavicular line; no pericardial friction. May 16th: Patient immensely improved; no dyspnoea; temperature normal; no abnormal constituents of the urine; apex beat in the fifth intercostal space, medial to midclavicular line; systolic murmur in mitral area much less intense. May 25th: Tonsillectomy performed; tonsils enlarged and septic. May 29th: Further outbreak of impetigo on the face. On June 3rd the patient was discharged from hospital, her general condition being good. The systolic murmur was still present, but much reduced in intensity; there were no abnormal constituents of the urine.

This case demonstrates a majority of the phenomena to which invasion of the body by haemolytic streptococci can give rise. A patient admitted to hospital with chorea, a typical rheumatic manifestation, subsequently develops a rash which, to all intents and purposes, is a typical scarlatiniform eruption; this, in turn, is followed by an outbreak of impetigo contagiosa. Almost immediately afterwards signs of cardiac involvement appear, accompanied by tonsillitis, and a few days later the patient has developed an attack of acute nephritis. Examination of the throat swab reveals the presence of haemolytic streptococci; there is a positive reaction to the intradermal injection of an extract of haemolytic streptococci, and the Dick reaction is negative. A further point of interest is the history of a "cold" three weeks before the onset of choreic symptoms. Glover and Griffith⁴ have shown that febrile and feverish colds are often a definite manifestation of haemolytic streptococcal infection. If it be assumed that this "cold" was such an infection, then the case is in the same category as those described by Collis⁸ and Sheldon,⁹ where rheumatic relapses were usually preceded by a tonsillitis of haemolytic streptococcal origin occurring one to three weeks before the rheumatic manifestations appeared.

CASE II

A boy, aged 15, was admitted to a surgical ward of the Royal Infirmary, Edinburgh, on March 12th, 1932, with a history that five years previously he had been in hospital for

several months on account of a "poisoned leg" following upon a cut on his foot. He was quite well after this until seven weeks before admission to hospital, when his right leg became very painful at the site of the old injury. The boy was found to be suffering from an acute osteomyelitis of the right tibia, which proved to be due to a haemolytic streptococcus. After operative treatment he made a good recovery. The case notes were as follows. On April 12th the patient was transferred to the Astley Ainslie Institution, a convalescent hospital. April 14th: Temperature 101.8°, pulse 120; scarlatiniform rash over whole body; no sore throat; foul discharge soaking through the elastoplast bandage; discharge contained *Staphylococcus aureus* and *albus*, and haemolytic streptococci. April 15th: Temperature 103.2°; rash fading. April 25th: Temperature 100°; pain in left wrist and hip; swelling on dorsum of hand; left border of heart 1 1/4 inch external to nipple line; mitral systolic murmur; salicylates administered and antistreptococcal serum. May 2nd: "Serum rash." May 6th: Pain in right hip. May 8th: Temperature 102°; heart enlarged; aortic systolic murmur. May 10th: Red patches on leg round wound; ? erysipelas. May 29th: Heart still enlarged; mitral and aortic systolic murmurs. June 2nd: Skin reactions to the intradermal injection of an extract of stock haemolytic streptococci and to an extract prepared from the culture of haemolytic streptococci isolated from his own wound both positive; Dick reaction negative; haemolytic streptococci isolated from throat swab. July 4th: Injections repeated; reactions still positive; Dick reaction negative; no haemolytic streptococci isolated from throat. July 22nd: Patient discharged, much improved; apex beat in nipple line in fifth interspace; mitral systolic murmur, and reduplicated second sound in pulmonary area.

Here again in one patient is practically the whole range of the clinical phenomena of infection with the *Streptococcus haemolyticus*. First the local infection, manifesting itself as acute osteomyelitis; then the generalized intoxication characterized by a scarlatiniform rash, followed by what some would regard as the allergic phase showing itself as acute rheumatism; and, finally, a localized invasive phase, characterized apparently by a mild attack of erysipelas. That the joint and cardiac involvement in April was a rheumatic manifestation is suggested by the prompt response to salicylate, and the subsequent progress of the condition.

CASE III

This patient, a girl aged 12, was admitted to the Ear, Nose, and Throat Department of the Royal Infirmary, Edinburgh, on March 16th, 1932, with the following history. There had been an intermittent discharge from the left ear since she was 8. At the end of February, 1932, she had been taken ill with "influenza," and on March 6th she had again complained of pain in this ear, which was followed by a discharge. Subsequently a discharge, unaccompanied by pain, appeared from the right ear. There had been no vomiting or giddiness. There was a history of tonsillectomy five years previously, but no history of rheumatism.

On admission the patient complained of pain in the left ear, which contained some pus. The tympanic membrane was bulging, and there was mastoid swelling and tenderness. Examination of the throat showed that a small piece of the right tonsil had been removed; the left tonsil was still entirely present. The tonsillar lymphatic glands were much enlarged, and there were large adenoids. The progress notes were as follows.

March 17th: Schwartz operation on left ear; sinus healthy. Growth of haemolytic streptococci obtained from pus from antrum. March 29th: Adenoids removed. April 4th: Temperature 102.2°, pulse 120; profuse discharge from both ears. April 5th: Schwartz operation on right ear. April 6th: Temperature 103.4°, pulse 140; no rigors. April 7th: Left jugular ligation; haemolytic streptococci isolated on blood culture. April 11th: 10 c.cm. scarlatina streptococcus antitoxin intravenously and 10 c.cm. intramuscularly. April 12th: 10 c.cm. antitoxin intravenously. April 13th: 25 c.cm. antitoxin intravenously. May 13th: Patient transferred to the Astley Ainslie Institution; still some discharge from right

mastoid wound. June 6th: Patient complained of pain in lumbar region on walking, which responded to rest in bed. June 10th: Again complained of pain in lumbar region, and was put back to bed; temperature 97°. June 11th: Temperature 99.6°; salicylate administered. June 16th: Temperature 98°; patient allowed to get up. June 23rd: Salicylate stopped. July 13th: Operation wounds healed.

August 4th: Temperature 98°; throat inflamed and tonsils swollen; complained of sore throat; systolic murmur in mitral area audible for first time. August 5th: Temperature 102°. August 13th: Temperature 98°; patient allowed up; throat normal; mitral systolic murmur still present. September 13th: Tonsils again septic. October 21st: Patient transferred back to Royal Infirmary; still complaining of pain in back; tonsils septic. October 29th: Tonsillectomy performed. October 31st: Patient transferred back to Astley Ainslie Institution; throat clear. November 28th: No haemolytic streptococci isolated from throat swab; negative skin reaction to intradermal injection of extract of haemolytic streptococci. December 12th: No haemolytic streptococci isolated from throat swab; skin reaction to injection positive. December 23rd: Patient discharged; mitral systolic murmur still present.

In this case a definite haemolytic streptococcal infection was followed by what must be considered as a rheumatic infection of the heart. Not only was the haemolytic streptococcus isolated from the local infection, but it was also obtained on blood culture. There was no family history of acute rheumatism nor had the patient herself ever previously shown any signs of a rheumatic infection.

CASE IV

A woman, aged 26, whose first child was born on December 30th, 1931, was admitted to a fever hospital on January 7th, 1932, as a case of puerperal fever. She was discharged on March 1st. On April 2nd her temperature was 101°, and she complained of pains in the knees, thighs, arms, shoulders, and right iliac fossa; these responded to salicylate. She was admitted on April 22nd to the Gynaecological Department, Royal Infirmary, Edinburgh, on account of pain in the right iliac fossa. The tonsils were enlarged. A diagnosis of pyosalpinx was made, and she was discharged on this occasion on May 10th. For four weeks in August she was in bed at home with a recurrence of acute rheumatic polyarthritis.

On November 6th she was readmitted to the Royal Infirmary on account of persistent pain in the right iliac fossa, and of pain in the "small of the back" and on micturition. The joint pains still persisted to a slight degree. On admission there was a blowing systolic murmur of the heart, maximal in the mitral area. The tonsils were large and ragged. The case notes were as follows.

November 8th: Subtotal hysterectomy performed; haemolytic streptococci isolated from pus from pyosalpinx; pains improved considerably after the operation, and in addition salicylate was administered. December 3rd: Patient transferred to Astley Ainslie Institution. December 12th: Haemolytic streptococci isolated from throat swab; skin reaction to intradermal injection of extract of haemolytic streptococci strongly positive. January 4th, 1933: Haemolytic streptococci isolated from throat swab; skin reaction to injection strongly positive; patient receiving salicylate; joint pains easier. January 23rd: Haemolytic streptococci present in throat swab; skin reaction still strongly positive; patient getting up for a short time each day; pains now absent. February 6th: Haemolytic streptococci isolated from throat swab; skin reaction positive to injection; loud, blowing systolic murmur still present in the mitral area; patient now up all day.

In this case the haemolytic streptococcal infection took the form of an attack of puerperal fever, followed by a pyosalpinx, which, on bacteriological examination, was found to be due to this organism. Here again there was no previous history of acute rheumatism, nor any family history, and it was only after a haemolytic streptococcal infection that an initial attack of acute rheumatism occurred, leaving in its train a definite cardiac lesion.

Discussion

If it is assumed, as is indeed probable, that the "cold" reported in Case I was a haemolytic streptococcal infection, then in each of the cases the rheumatic manifestations were preceded by such an infection. Another feature of all four cases is the absence of a previous history of rheumatic infection and of any family history of this disease. On the other hand, there is much variation in the period intervening between the onset of the haemolytic streptococcal invasion and that of the rheumatic manifestations. In view of the clinical picture and the response of these cases to sodium salicylate, there can be little doubt that the cardiac and arthritic signs were of rheumatic origin.

It must be borne in mind, however, that this is not a random selection of cases. For every case here reported there were many more where either haemolytic streptococcal infection was present without associated rheumatism, or acute rheumatism existed without any evidence of haemolytic streptococci being involved, although the former was the more common finding. In other words, haemolytic streptococcal infection without any accompanying or consequent rheumatic manifestations was much more frequently found than acute rheumatism without some evidence of haemolytic streptococcal involvement. This is a factor which is of the greatest importance in any attempt to assess the role of the haemolytic streptococcus in the aetiology of acute rheumatism. It has been pointed out elsewhere¹¹ that if any series of cases of haemolytic streptococcal infection be examined the majority of cases of acute rheumatism in the series will be found to be secondary to such infection, whereas in a series of cases of acute rheumatism the number of cases secondary to haemolytic streptococcal infection will be much smaller.

The cases here reported are deliberately chosen because of the dominant part played by the haemolytic streptococcus, and in order to emphasize the important, though perhaps not primary, role of this organism in the aetiology of acute rheumatism, a role which must always be considered in any attempt to investigate the aetiology of this disease. That a close association does exist between the haemolytic streptococcus and acute rheumatism is exemplified even in this short series, where the latter condition was found in association with: (1) tonsillitis, (2) otitis media, (3) mastoiditis, (4) puerperal fever, (5) pyosalpinx, (6) acute nephritis, (7) acute osteomyelitis, (8) erysipelas, (9) impetigo, and (10) scarlet fever, in each case haemolytic streptococci being isolated as the causal organism. To argue from this, however, that the micro-organism is the primary cause of acute rheumatism is not valid, in view of the much larger number of cases in which no evidence of acute rheumatism is ever found.

The value of the cases in this series is further enhanced by reason of the fact that in none was there any family or previous history of acute rheumatism; it is not possible to argue, therefore, that we are here dealing with the invasion of tissues already susceptible to the disease. Again, the period elapsing between the first signs of haemolytic streptococcal invasion and the onset of the rheumatic manifestations is so variable that it argues strongly against the haemolytic streptococcus being the primary cause of the disease.

As suggested elsewhere,¹¹ the present position would seem to be one of two alternatives: either that infection with the haemolytic streptococcus facilitates the invasion of the tissues by some specific agent, or that the haemolytic streptococcus may so alter the tissues susceptible to rheumatic infection as to prepare the way for invasion by this specific infective agent.

I have to acknowledge my great indebtedness to Lieut.-Colonel John Cunningham, superintendent of the Astley Ainslie Institution, not only for permission to study the cases under his charge and for full access to the case notes, but also for the sympathetic assistance which I received from him at all times. I am similarly indebted to Professor Charles McNeil for permission to publish the notes on Case 1. This work was part of a larger study of acute rheumatism which was being carried out in co-operation with Dr. H. J. Gibson of the department of bacteriology, and before my entrance to the Royal Navy, with the aid of personal and expenses grants from the Medical Research Council, and latterly during my tenure of the Davidson Research Fellowship in Bacteriology.

MENTAL DEFICIENCY AND HEREDITY

BY

F. GRUNDY, M.D., D.P.H.

ASSISTANT COUNTY MEDICAL OFFICER OF HEALTH, EAST SUFFOLK COUNTY COUNCIL

A little over a year ago I completed an investigation into the incidence and circumstances of retarded school children and mental defectives, which had for one of its objects the investigation of medical and family histories of all defectives of school age within a defined area. An attempt was made to estimate the relative importance of various factors in the causation of mental deficiency, and it is the purpose of this paper to give a brief account of this aspect of the original investigation. Other relevant matters are referred to from time to time, as appears necessary to the purpose in view. If in places this short contribution seems ragged, and poor in supporting evidence, indulgence is asked on the ground that it is the essence of a thesis some ten times its length, an important part of which was the presentation of genealogical charts which consideration of space precludes from reproduction here.

Introductory

The area referred to is the north-east quadrant of East Suffolk, with a total population of 45,435, a school population of 6,645, and a density of population of 0.3 persons per acre. The chief industries are agriculture and fishing. Communications across country are relatively poor, and many villages are still comparatively isolated. Social cohesiveness is high throughout the area, and remarkably complete family histories were obtained; as a rule, without great difficulty. The standards employed were those fully described by Dr. Lewis in his report.¹ A total of 750 children (11.2 per cent. of the entire school population) was examined by individual methods, and there is every reason to believe that the ascertainment of defectives was, for practical purposes, complete. Stanford tests and Burt's graded tests were used respectively in the estimation of mental and of educational age. The investigation of suspected defectives of school age followed closely that usually undertaken in the completion of Form 306 M. of the Board of Education; that of suspected adults was made with the social concept of deficiency in mind. It was neither practicable nor indeed desirable to subject adults to systematic testing.

While it is clearly impracticable to submit any details of individual cases, it may be said generally that judge-

ments relating to school children were based on precise observed facts, those relating to parents on personal observations, and those relating to other members of a family on strongly presumptive evidence, corroborated whenever possible.

Total Ascertainment and Family Histories

A total of 165 ascertained defectives of school age was made up of 135 feeble-minded, twenty-three imbeciles, and seven idiots, a proportion almost identical with that found by Dr. Lewis in rural areas.² The close correspondence is a matter of importance, because it raises a presumption that no great disparity existed between the standards employed in the investigations.

The incidence of mental defect and retardation ran hand in hand, and the essential feature of loci of high incidence of both was their degree of social isolation. There was no ground for believing that this factor operated directly, but it was, in all probability, the biggest cause of migration from such areas to others of greater social amenity, a movement most affecting the better stocks of higher initiative. Consequently, the proportion of inferior stocks in these areas was increased, and the incidence of deficiency rose *pari passu*.

A total number of 116 family histories was investigated, twenty-eight of which were not full enough to permit conclusions being drawn with any confidence. No fewer than 149 of the ascertained defectives of school age were involved in the family histories, leaving only sixteen, all of feeble-minded grade, in whose cases a family history was unobtainable. It is convenient here to present summary pathological and aetiological classifications based on the medical and family histories.

Pathological Types

Imbeciles and Idiots		Feeble-minded	
Mongolians ...	9	Infantile encephalitis ...	2
Meningitic ...	1	Traumatic (birth injury) ...	1
Hydrocephalic ...	1	Simple primary ...	132
Epileptic ...	1		
Simple primary ...	18		
Total ...	30	Total ...	135

Causation

Imbeciles and Idiots		Feeble-minded	
(a) Environmental factors	6	(a) Environmental factors	4
(b) Without apparent cause	17	(b) Without apparent cause	10
(c) Prima facie evidence of a hereditary factor	7	(c) Neuropathic inheritance	71
		(d) Combination of neuropathic inheritance and environmental factor	15
23 per cent. attributable to inheritance.		71 per cent. attributable exclusively to neuropathic inheritance.	

No further comment need be made on Group (a), and it will be sufficient to say of Group (b) that cases under this heading could not be referred to a cause, although reasonably complete information was available. It is likely that a fuller knowledge would have led to their classification with those due to environmental causes.

It is necessary now to indicate the nature of the evidence which was taken into account in the selection of cases attributed to neuropathic inheritance, either alone or combined with an environmental factor. Very briefly, inheritance was regarded as a factor in causation in the presence of: (a) several defective siblings; (b) defectives or other marked neuropaths in antecedent generations, especially defectives or borderline parents. Without elaborate statistical methods, themselves not beyond criticism by statisticians, conclusive proof of hereditary influence cannot be offered, but it is noteworthy that other workers who have used the method of family surveys have reached substantially the same conclusions as those presented here. A glance at the family charts referred to would give a very fair notion of the standard of judgement employed, but a personal acquaintance with the families in their usual environmental setting is by far the most convincing evidence. It is hoped that the following numerical summaries will give some idea of the features of the family charts of feeble-minded children whose amentia was attributed to neuropathic inheritance.

Number of defective sibs (a) in family	1	2	3	4	5	6	6+
Number of families	19	4	7	5	1	—	—
Total (b) size of sibship	1	2	3	4	5	6	6+
Number of families	5	8	8	9	4	—	2

$$\frac{\text{Number of unsatisfactory (c) siblings}}{\text{Total number (b) of siblings}} = \frac{58}{121} = 73 \text{ per cent.}$$

$$\frac{\text{Number of defective or borderline (d) parents}}{\text{Total number (b) of parents}} = \frac{43}{66} = 60 \text{ per cent.}$$

(a) "Sibs" means siblings in family of an ascertained defective of school age. (b) Total number does not include those who were not assessed either because they were inaccessible, or in the case of children too young. (c) "Unsatisfactory" means defectives, borderline cases (I.Q. less than 80 per cent.), dead during infancy, and stillborn. (d) "Borderline" means illiterate dullards who were almost certainly defective in an educational sense during childhood.

Feeble-mindedness was judged to be due to the combined influence of hereditary and environmental factors where, in the presence of a neuropathic family history, only one of many siblings was actually defective, whereas several others were of poor mental quality, although not actually defective. It seemed that a factor, sometimes suggested by the history; additional to the neuropathic inheritance had operated to produce an actual defective among a group of poor quality siblings.

Lower-grade Deficiency and Heredity

It will have been remarked that in 86 per cent. of the feeble-minded there is evidence of hereditary influence alone or in combination, in contrast with a *prima facie* 23 per cent. of lower-grade aments. Dr. Lewis, who reached a similar conclusion after a more extensive investigation, says: "Lower-grade deficiency is not a family problem to the extent that some previous writers have led us to expect." If all grades of defectives are considered together 75 per cent. appear to be associated with a neuropathic inheritance. As the incomplete histories, which all refer to feeble-minded persons, are not taken into account in this estimate, it follows that the proportion of cases in which hereditary influence plays a part is somewhat underestimated, for an undue proportion of lower-grade defectives is admitted.

Dr. A. F. Tredgold, referring to defectives of all ages, types, and grades, estimates that in approximately 80 per cent. the condition is due to inheritance.³ He points out that inquiries which are confined to children will show a relatively greater number due to environment, because lower-grade cases, in which the expectation of life is considerably less than in higher-grade cases, are due, for the most part, to environmental causes. Bearing in mind the omission of many incomplete family trees of higher-grade defectives, the restriction of the initial ascertainment to children, and the relatively small number of cases, the present estimate appears to be in close agreement with that of Dr. Tredgold.

It is important to realize that the majority of feeble-minded children are merely profound dullards, distinguished from those usually classed as "dull and backward" by a purely arbitrary borderline. Such deficiency has no pathology in the ordinary sense of the word, and the subjects thereof are represented by the extreme left of a frequency distribution curve of intelligence quotients. They are quite properly regarded as the analogues of short individuals of say five feet, in a community of average height 5 feet 6 inches, in which a few members attain heights of 6 feet. It is among this group and not among definite pathological types that hereditary influence is so prominent.

According to my own investigations twelve out of thirteen children certifiable as feeble-minded according to educational standards are well behaved during the years of school life, and exhibit no distinctive abnormalities of character other than apathy and undue docility.

Furthermore, roughly half the children certifiable as defectives for the purpose of the Education Acts will not be defective in a social sense in adult life in a rural area.⁵ That is to say, there exists a wide disparity between the standards used in the educational and social classifications of feeble-mindedness, and it is difficult to avoid the conclusion that the use of the single term "feeble-minded" in two distinct senses, both of which are legal and not scientific, is highly confusing in an inquiry of this sort. An attempt was made to overcome the difficulties implicit in this duality of meaning, but finally a conviction was established that nothing short of a carefully planned genealogical survey, extending over at least two generations, would meet the case. Be that as it may, a study of families containing defectives enabled certain principles, which are summarized below, to be advanced tentatively, yet with the knowledge that they are consistent with, and lend support to, many widely known authoritative opinions.

Summary of Conclusions

1. Roughly 75 per cent. of defectives of all grades come of stocks which exhibit distinct mental abnormalities, of which deficiency and gross dullness are the commonest.

2. Of the remaining 25 per cent., a few are attributable to environmental causes, but most are without apparent cause.

3. Feeble-mindedness and dullness are familial to a much greater extent than lower-grade deficiency.

4. The mating of two mentally defective individuals yields offspring who are all defective.

5. The mating of two individuals of "poor type" yields offspring of "poor type," who are often defectives in an educational and sometimes in a social sense.

6. "Dull parents, dull children," is a usual association.

7. When a neuropathic stock exists the chance presence of an adverse environment, using the term in its broadest sense, may produce actual deficiency in cases which might not have been defective without the intervention of such a factor.

Clinical Memoranda

PERFORATIVE APPENDICITIS COMPLICATING ACUTE NEPHRITIS IN AN INFANT

Acute appendicitis under 1 year is very rare, and under 6 months excessively so. Of 500 cases admitted to the Royal Infirmary, Edinburgh, there were but three in infants in the first year of life (Fraser¹; he does not give the exact ages in months). Pre-natal appendicitis is recorded by Jackson²; Kümmell, quoted by Lipshutz,³ records appendicitis in a baby who died twenty-four hours after birth. Abt⁴ has made what is probably the most exhaustive survey of the literature, and has collected records of seventy cases in children under 2 years, twenty being in infants under 3 months. Reports by other observers covering a large series of cases show a similar striking paucity of references to appendicitis in infants less than a year old. Fraser⁵ gives an anatomical and bacteriological explanation for this. (1) There is a very small amount of lymphoid tissue in the appendix at birth, and it gradually increases; the presence of this tissue seems to render the locality in which it resides more prone to infection. (2) The *B. coli communis*, which is the infecting organism in the majority of cases, shows great variation in virulence; just after birth it is very slightly toxic, but this feature becomes more marked as the child grows older, probably caused by change in diet and in some cases by attacks of gastro-enteritis, mild or otherwise. The following case is therefore of interest.

A female, aged 5 months, was admitted to hospital on December 5th, 1933, suffering from general oedema. We could ascertain nothing beyond a history of a rash six weeks previously; there had been measles in the family, and this probably accounted for the rash. (Appendicitis has been quoted as a complication of measles by some observers, and Thencebe, Hirshberg, and Cenci⁶ have reported six cases, but in none of them was the patient under 5 years; it is doubtful, of course, if there is any real connexion in this case.) The urine was scanty and loaded with albumin, and a diagnosis of nephritis was made. On December 7th no urine was passed, and on the following day 1½ c.cm. saliorgan was given, which produced a copious flow. Urine was passed freely on December 9th, but was scanty again the following day. The saliorgan was repeated on December 11th, and the flow again became copious. On December 12th the child passed urine freely and appeared much better; on December 13th and 14th the urine was freely passed, but saliorgan was repeated on the 14th. The child died on December 15th.

The temperature was 99° F. on admission, 100° on the sixth day, and rose to 104° on the seventh; it continued between 102° and 103° until death, when it rose to 105°. The stools were green and slimy on admission, but became normal after three days until the last two days, when only mucus was passed. Owing to the difficulty of obtaining a specimen of urine no record was made of the amount passed. The usual methods of producing diuresis—hot packs, etc.—had no apparent effect. The abdomen was examined on a few occasions, but beyond being oedematous—and this was improving—there was nothing else to be noted; the child slept fairly well, and took its feeds.

At necropsy the kidneys showed the features of a nephritis; they were not enlarged, but were congested, cortex thinned, and there were spots of haemorrhage scattered through the medulla. Beyond some slight congestion of the lungs the other organs were normal. On looking into the pelvis pus was discovered, and on further investigation the appendix was found to be perforated at the base; the pus which had gravitated anterior to the rectum was odourless, and there were no obvious signs of peritonitis. The brain was not examined, as the parents did not wish the child's head or face to be disfigured.

There is no record, so far as I am aware (but this is subject to correction), of appendicitis complicating acute nephritis in an infant. In this case it was an absolutely silent appendix: Lipshutz remarks that infants with appendicitis always vomit, but this feature was absent; the infantile peritoneum is said to be very susceptible to infection, and a general peritonitis rapidly develops, but this did not occur. Which condition killed the infant—the nephritis or the appendix? And am I correct in assuming that the rise of temperature marked the entrance of the appendix to the picture? The case is interesting, and I should like the comments of those more experienced than myself.

I am indebted to Mr. E. S. Gawne, F.R.C.S.Ed., medical superintendent, for permission to publish this case.

Reviews

PATHOLOGICAL ANATOMY.

Having already brought out a work on general pathology, Professor DIETRICH now follows it with a volume on pathological anatomy.¹ It has been customary in works on pathological anatomy to start with a section on general principles as a necessary introduction to the proper understanding of the special section, to which it was more or less subordinate. In recent years the interest in the general section has greatly increased, until, as in Professor Dietrich's work, it has come to occupy an independent position, the interest in pathological anatomy in the narrower sense having declined. The tendency now is to regard the special part merely as giving typical examples in illustration of general principles, avoiding the overcrowding of descriptions with anatomical details amid which a sense of relationship to general principles is apt to be lost.

Professor Dietrich has followed out this idea in his book, the chief difficulty encountered consisting in the choice of subjects to be included. Certain subjects will be looked for in vain, and some descriptions may be thought unduly concise; in these matters it is left to the student to fill in details from other sources. While thus limiting the range of pathological anatomy in this particular instance, Professor Dietrich has no doubt of the great importance of the subject for the general practitioner. It provides a solid basis of fact, entirely free from theory and from the danger inherent in a purely functional point of view which, unsupported by pathological anatomy, easily leads to speculation.

In other respects the book follows the usual lines. In addition to the description of pathological changes the author has been careful to give full consideration to the interrelationship of lesions, regarded as the cause or consequence of other lesions, as originating reactive changes in other parts of the body, and as merely independent associated changes. It will be found a useful book both to student and to practitioner.

CAUSES OF MENTAL DEFICIENCY

The results of an interesting piece of research are recorded in *Investigations into the Causes of Mental Deficiency*,² by Dr. H. O. WILDENSKOV, translated from the Danish by Dr. Hans Andersen. Dr. Wildenskov is the medical superintendent of the Keller Institution for Mental Defectives at Brejning, Denmark. In the course of his work he, like most others, has been convinced that thorough inquiry into the family history of a mental defective constitutes an absolute prerequisite for an estimation of the cause of the defect. Further he, again like others, has become convinced that there is a marked difference in the apparently hereditary associations of the milder degrees and the more severe forms. He says: "Other investigators have also recognized that there is an essential difference between the two groups, but I have not yet found in the literature any particularly systematic investigation aiming to elucidate the possible difference"; and, "If there be actually a difference of causation between the mild degree and the severe degree it would be apt to influence the results obtained by the various

investigators, since the selection of material by itself would thus bring about some difference in the results." The author therefore took two groups of mentally defective persons, entirely from his own institution: consecutive entries respectively of children admitted to the school departments, and therefore presumably of the milder type (dullards and feeble-minded), and of children admitted to the asylums department and therefore presumably of the more severe type (imbeciles and idiots). A full and skilful investigation was made by the author himself into the families of these groups, and though by this method both expert knowledge and uniform standard were ensured, the number of cases that could be made the subject of inquiry was necessarily much restricted. Only fifty in each group were finally included in the research.

The results are analysed very carefully in many directions, and an account of the actual cases, together with the results of this analysis, is given in Dr. Wildenskov's report. The findings show that there is a great difference in the results obtained with the two classes of mental defectives, mild and severe. There is a lower social and moral standard in the families of the slightly mentally defective. The hereditary taint is demonstrated considerably more often in the mild cases than in the severe (98 against 74 per cent.), and oligophrenia in the nearest relatives is shown to be far more frequent in the milder group (90 to 60 per cent.). The author is, of course, "fully aware that the question of causation is not settled by the findings in this work," but the practical conclusion is arrived at that "future works on mental deficiency ought to be based on material that is uniform as to the degree of mental deficiency." There is a useful bibliography and an interesting review of recent literature relevant to the investigation.

STUDIES IN METABOLISM

The discussion of Nitrogenous Metabolism³ by Professor E. F. TERROINE is the eighteenth in the series of monographs on biological problems which is being published by Les Presses Universitaires de France. The author, a distinguished authority on comparative metabolism, deals with the absorption, utilization, and excretion of nitrogen, while a large section of the volume is devoted to a consideration of the minimum nitrogenous requirements viewed from both the quantitative and the qualitative aspects. The scope of the volume is very large, for it includes not only the greater part of ordinary quantitative metabolism, but also discusses the minimum needs of the body for special amino-acids, a problem closely linked with vitamin studies. The author has covered this wide range of topics in a volume of 562 pages, and his bibliography contains about 900 references. These figures imply a very condensed account of the subject, and, indeed, much of the letterpress is occupied by tables which summarize the results of metabolic experiments. Consequently the volume is more suitable for reference than for continuous reading. This general character of the monograph makes it the more unfortunate that no index has been provided.

Professor Terroine, in the section on dietetics, draws attention to the curious paradox that physiological research during the last half-century has steadily reduced the level of the minimum protein requirements of man. In 1875 Voit estimated the figure to be 120 grams a day, whereas modern researches have shown that it is possible to maintain nitrogenous equilibrium on a daily intake of from 30 to 50 grams of protein. On the other hand, all

¹ *General Pathology and Pathological Anatomy*, By H. O. Wildenskov, M.D., Professor Dr. Albert Dietrich, 1931. 8 Hurd 194 (Rp. 413); 252 pages, R.M.1850.

² *Investigations into the Causes of Mental Deficiency*, By H. O. Wildenskov, M.D., Copenhagen: Levin and Munksgaard; London: H. K. Lewis, Oxford University Press, 1934. (Rp. 115)

classes or races have increased their protein intake whenever this has been made possible by improved economic conditions. The author thinks this a disconcerting fact, and remarks that "this is not the only example of the irrational character which human diet assumes more and more, even though the rules which ought to govern it are steadily becoming clearer." One fairly obvious reason for such discrepancies is that the physiologist recommends a diet on the basis of its fuel value, whereas the ordinary individual chooses so far as possible a diet that will gratify his appetite and taste.

The volume contains an excellent review of various special problems of protein metabolism, such as its relation to hair growth, milk secretion, egg-laying, etc. The section on requirements in regard to individual amino-acids touches various problems of pathology. In particular there is an interesting account of work on the influence of amino-acid feeding on haemoglobin formation in anaemia.

EFFECTS OF MOTION PICTURES

The Payne Fund of New York City, through its committee on educational research, has been engaged during the greater part of the last five years in the gathering of facts and experience with regard to the effect of motion pictures on youth. The results of these investigations are now in course of publication. A note on a volume dealing with the effects on children's sleep was given in these columns on February 24th last (p. 335), and additional volumes are now forthcoming: *How to Appreciate Motion Pictures*,⁴ by EDGAR DALE; *Motion Pictures and Youth*,⁵ by W. W. CHARTERS; and *The Emotional Responses of Children to the Motion Picture*,⁶ by WENDELL S. DYSINGER and CHRISTIAN A. RUCKMICK of the University of Iowa.

The first of these three volumes is by way of being an introduction to the series. It has no medical bearings, but is, in fact, a very interesting and informative help to the inexpert, and fulfils admirably the purpose indicated by its title. The other volumes exhibit the usual virtues and vices shown as the results of the modern American method of conducting an inquiry through a large committee with a considerable fund at its disposal and publishing results with voluminous detail and comment. The inquiry is usually—as in this instance—most laborious and painstaking, but the subject is not always fully ripe for research, the methods are not always wisely chosen, the conduct of the inquiry and the estimation of its findings are not always free from apparent bias, and statistical statements are not uncommonly based on too small a sample. Hence the results of such an inquiry as set out with laborious particularity in a series of reports are frequently of no real scientific value and are quite disproportionate to the trouble that has been taken by the large number of people concerned. Yet, if final scientific proof by facts and figures may still be wanting, certain broad impressions produced by such American inquiries as those now under consideration may not be without their value.

With regard to the effect of motion pictures on the minds of children and young persons, both in relation to intelligence and in relation to emotion, certain definite broad impressions seem to have been produced on all those who took part in these inquiries. They are set

out in the main chapter of each of the two volumes. In the first place, even very young children remember clearly what they see for many weeks after the event, and all children tend to accept as authentic what they are shown. Thus the motion picture is a potent influence in moulding the experience of children; it may be made a powerful medium of education, but the content of current pictures is not found to have a good influence. Further, the investigators report that, as gauged by their school teachers, the children who attend "movies" very frequently average lower deportment records, do on the average poorer work, are rated lower in reputation, are less co-operative and less controlled, and are slightly more deceptive in school situations, slightly less skilful in judging what is the most helpful and sensible thing to do, and slightly less emotionally stable. But many important questions at once arise before these statements can be accepted. The authors themselves put one of them: "Does extreme movie attendance lead to conduct which harms reputation, or do children of low reputation go frequently to the movies?"

Those who wish to follow more fully the methods and facts from which such impressions as these resulted cannot do better than study the books now under review. It may safely be predicted that, though in most such readers a good deal of disquietude will be aroused, there will at least be some who will not be fully convinced that definite conclusions are yet justified.

OPERATING ROOM PROCEDURE

The volume on *Operating Room Procedure* by Dr. HENRY C. FALK, first published in 1925 and now appearing in a second edition,⁷ aims at giving those who assist in an operating theatre all the technical information they require. Every surgeon realizes that with the great advances of modern surgical technique he has become more and more dependent upon the technical knowledge and skill of his assistants, but probably very few realize the immense amount of preparation that underlies a simple operation. It is just these details which are supplied in this volume.

Every hospital has, in the nature of things, developed its own traditions for the preparation of operating materials; but here will be found, described in most precise detail, all the best-known methods, and we imagine that there are very few theatre sisters, however experienced, who will not glean from it some useful suggestions. The preparation of gauze supplies, of suture material, of gloves, and rubber appliances are all described in elaborate detail, whilst a valuable chapter is devoted to the systematic keeping of supplies. The preparation of the patient and his adjustment on an operating table are discussed by the author with great thoroughness and illustrated by very precise sketches, which seem to us of real value.

The second half of the book is devoted to details of operation which a nurse or an assistant ought to know in order to take an intelligent interest in what is being done. The whole of this section is illustrated by rough thumbnail sketches, which leave one in no doubt as to the meaning they are intended to convey. Dr. Falk's book should be of great value to theatre sisters and nurses, and, in fact, to all those who have to assist at any operation. Indeed, there are few surgeons who would not pick up valuable hints from its perusal.

Notes on Books

The third edition of Professor McDOWALL's book on *The Science of Signs and Symptoms*¹ has appeared two years after the first edition, amplified in size and in scope. It is written as a textbook for general practitioners of medicine, and its object is to correlate the latest views of physiological science, using that term in its widest sense, with the bedside findings of clinical science. The first quarter of the volume deals with the nervous system in its various normal and abnormal aspects, with chapters on such subjects as sensation, headache, convulsions, speech, and so forth. Next, the circulatory and respiratory systems are considered, and after them foods, feeding, digestion, and the digestive system. In the final chapters subjects such as growth, oedema, the skin, acid-base equilibrium, and others are discussed, a final chapter on "The Psychological Production of Symptoms" being contributed by Dr. Hardcastle. The book may be warmly recommended to the attention of medical practitioners who are anxious to bridge the gap that is so often found to separate the principles of physiology from the daily practice of clinical medicine. It is clearly written, comprehensive, and not over-dogmatic.

The short textbook on Tuberculosis of the Lungs² by GISEL and SCHMIDT gives a short history of the disease and a full account of the tubercle bacillus and of the ways in which it may attack the lungs. The symptoms, diagnosis, and treatment of pulmonary tuberculosis are described, with especial emphasis on the various methods of surgical treatment that are nowadays of increasing importance. The book is well written, and illustrated with many excellent skiagrams; it is up to date, and may be recommended to medical men and surgeons who wish to refresh their memories by reading a recent variation on an old theme.

The series of *Médecine et Chirurgie Pratiques* includes a monograph on Bronchiectasis by Dr. MICHEL LÉON-KINDBERG.³ The disease is described from every aspect, but a very large part of the book is devoted to a somewhat speculative but highly interesting discussion on the aetiology and pathogenesis. The author shows how much knowledge of the disease has been increased by a study of the bronchial tree with the aid of lipiodol and x rays. A number of excellent reproductions of films illustrate points in pathology and diagnosis. An interesting point is the true significance of the square or triangular shadows interpreted as showing posterior mediastinal pleurisy. By the aid of lipiodol it has been demonstrated that there is usually bronchiectasis, which is in accord with the clinical symptoms and signs. The author ends with a sketch of the treatment, and concludes from a large experience, that the indications for artificial pneumothorax, resection of the phrenic nerve, and thoracoplasty are very restricted. Lobectomy presents almost insuperable obstacles at the present time, though it has given some remarkable successes. He believes that most benefit is to be obtained by relying on palliative treatment, including bronchoscopy, which sometimes cures the patient permanently.

We welcome the second edition of Dr. CRANSTON LOW's *Common Diseases of the Skin*.⁴ It maintains all the excellent qualities which were to be found in the original work, and has been considerably improved and brought up to date. The number of illustrations has been more than doubled, and their quality—always a matter of vital importance in any dermatological book—is very high. Dr. Cranston Low is thoroughly modern in his outlook, and

all the more recent methods of treatment are included, with the exception, perhaps, of protein shock, of which there appears to be no mention, although good results had been obtained from it in many forms of chronic dermatoses. This is a very sound introduction to the subject, and may be again recommended both to students and to medical practitioners.

In his statistical account of the reduction of infantile mortality in Norway⁵ between the years 1867 and 1929, Dr. C. SCHIÖTZ discusses the figures furnished by the Norwegian Central Statistical Bureau from every point of view, and compares them with many similar records drawn from other countries. The death rate during the first year per 10,000 born alive has fallen from 1,269 to 568 in the case of boys, and with girls from 1,066 to 443 during this period; the death rate is always higher (by 19 to 28 per cent.) for boys than it is for girls. January and February are the most fatal months for infants; September is the least fatal. Many interesting points are discussed in this book, which may be recommended to the attention of medical statisticians.

The little book on Gangrenous Suppuration of the Lungs,⁶ by BERNARD and PELLISSIER, gives an excellent general account of the classification, diagnosis, and treatment of the condition. The authors have obtained good results in a number of cases from "autopyotherapy"—that is to say, by treatment with a heated or iodized vaccine made from the pus of the abscess formed in a guinea-pig by the intramuscular injection of 1 to 2 c.cm. of the patient's sputum; this pus is diluted before injection with thirty volumes of distilled water, the initial dose being 0.25 c.cm., the final 1 to 2 c.cm. The volume may be recommended to all medical men who have to treat cases of pulmonary gangrene.

The work on *The Single Woman*⁷ by Dr. R. L. DICKINSON and Miss LURA BEAM forms a continuation of their previous study entitled *A Thousand Marriages*, and should be read in association with Dr. Dickinson's recently published *Atlas of Human Anatomy*, to which frequent reference is made throughout the text. The book is based on the study of 1,078 records of cases described at length, which have been under Dr. Dickinson's observation during the last fifty years. Numerous statistical tables are appended relating to the period of observation of the patients, comparative distribution of nervous disorders among married and single patients, occurrence of pelvic disorders, menstrual history, occupation of the patients, incidence of operations and nervous or mental disabilities, seasonal indications of sexuality, and signs of sexuality in various groups of patients.

New Preparations

BEE VENOM OINTMENT

In response to a reawakened interest in the employment of bee venom for the treatment of rheumatism, Messrs. Coates and Cooper, Ltd. (94, Clerkenwell Road, E.C.1), now stock supplies of "fempin" which has been used for some time on the Continent. Fempin is prepared in the form of an ointment, and is made in two strengths. No. 1 contains the venom of sixty-five bees and No. 2 contains the venom of ninety-eight bees. In addition, fempin ointment contains salicylic acid and oil of mustard. The manufacturers claim that its action is at least equal to the subcutaneous injection of bee venom, and that the application is simple and seldom attended by any danger to the patient. The price of the No. 1 is 5s. 6d. and of No. 2 ointment 4s. 6d. per tube. Samples are available for members of the medical profession who may be interested in this technique.

FOOD STANDARDS OF THE WORKING CLASS

A COMMITTEE AGAINST MALNUTRITION

Several members of the medical profession in London and research workers in allied fields have lately established a committee to be called the "Committee Against Malnutrition." Those who have started the movement believe that there exists in this country widespread under-nourishment among the families of unemployed and low-paid workers, that this must inevitably lead to a steady deterioration in the physical standards and health of the people, and that the last thing upon which a community must economize is the nutrition of its working class. The aim of the committee (which works from 19c, Eagle Street, Holborn, W.C.) is to give people throughout the country the opportunity of centralizing their information and co-ordinating all efforts to the end of securing adequate nourishment for every man, woman, and child. It publishes a bi-monthly bulletin and other literature, arranges lectures to organizations likely to be interested, and furnishes support to any direct campaigns for increase of food standards.

The first public meeting in connexion with the committee was held in Red Lion Square on June 13th, and was so largely attended that an overflow meeting had to be arranged at the last moment, to which all the speakers went to repeat their addresses. The chair was taken by Sir FREDERICK GOWLAND HOPKINS, President of the Royal Society, who declared that the outstanding social duty of the moment was to see that all sections of the people were properly nourished. This was even more important than to see that they were properly housed. Any housing policy should go hand-in-hand with a sound food policy. The paradox and scandal of to-day was the coexistence of abundance and want. Science and enterprise had reproduced on a large scale the miracle of the loaves and fishes, but these were not being fed to the multitude. Science, moreover, had shown the necessity of the fishes as well as the loaves. Even in a physical sense no one could live on bread alone, though margarine and subsidized beet sugar were added. The initial steps taken in this movement had been both wise and useful. As far as possible it should avoid all issues which were merely political. A number of highly influential men in Government circles were at the moment very much awake to the necessity of action if the further regression of this nation into a C3 nation was to be arrested; therefore, in respect to political action, he thought they should be a little patient. What had to be done was to remove certain inhibitions—apathy in a few, disbelief also in a few, and ignorance in a great many.

Dr. STELLA CHURCHILL spoke of malnutrition as affecting women and children. She said that some years ago she had attempted an elementary piece of research in Bermondsey, and found the most heart-breaking deterioration in young children between the ages of 1 and 5. The rickety girl of 5 was going to be the maternal mortality case of 25. With regard to women, she said that the mother in the working-class home was the last person to be fed. She knew of hundreds of homes where the woman was not getting enough food. She made the suggestion that floating kitchens should be organized for unemployed families, who, on the production of vouchers, would be entitled to have ready-cooked meals.

Dr. R. A. LYSER, lecturer in public health at St. Bartholomew's, said that the standard of existence of the unemployed depended upon the interpretation of various groups of men with no common factor. The Government on its part declared that it was the local authority which had the statutory obligation to provide food for the necessitous; yet there were large public assistance authorities which interpreted their duty very narrowly, and as the relieving officers told the unfortunate people that it was of no use applying, no applications came along—a very effective way of preventing anything being done. About a year ago public apprehension began to be aroused with regard to the nutrition of large classes of the popula-

tion. Various insurance bodies reported increases in the sickness rate, and the tuberculosis returns went up. But just when this public apprehension was making itself evident it was allayed by extracts from an official report published under the auspices of the Ministry of Health, which stated that there was no available medical evidence of malnutrition due to unemployment. If the Ministry of Health did not know of it, Dr. Lyster declared, the Ministry was the only place in England to remain in ignorance. The fact was that medical officers of health, in their ordinary reports to the Ministry, could only introduce the subject of malnutrition by, in a sense, going out of their way; it was not in the medical officer's general line of work. But that the facts warranted public apprehension there could be, no doubt. He urged that every child should be given half a pint of milk every day in the year, and the cost of so doing—about seven and a half millions per annum—would be the best investment the nation could possibly make.

Professor J. B. S. HALDANE said that the scientific knowledge of nutrition had got past the stage of theory to a stage where a fair number of facts were quite definitely known. The time had gone by when one could legitimately talk about theories of nutrition. There was now very substantial agreement about the facts, and therefore a laboratory worker like himself was not entirely out of place on the platform. As a result of the work on nutrition of the last thirty years it was possible to lay down a perfectly definite standard, quantitatively and qualitatively, for nutrition. After mentioning the various constituents of a proper food supply, Professor Haldane went on to say that when research made a standard possible it was time for public action. There was no question that the food was in existence, and the minimum standard of nutrition should be enforced, just as a minimum standard of water purity was enforced, as part of the public health service of the country. He added that there was taking place at the present time a mothers' strike, something quite as important as the general strike of 1926, but continuing, and the refusal to bear children would go on until it was recognized that the production of children was a national service, to be subsidized or to receive help from the State in some form. Not only in the interests of health, but in order to prevent a catastrophic decline in population, he gave his most cordial support to the movement of the committee.

When the meeting was thrown open to general discussion, Dr. ELWIN H. T. NASH said that he drew attention twelve years ago to the question of subnormal nutrition, and his voice was that of one crying in the wilderness until Dr. McGonigle of Stockton-on-Tees produced his classic report. While in no sense antagonistic to the present movement, he rather deplored some of the exuberant phrases which had been used. There was no standard of nutrition known at the present time. He thought it was desirable not to overstate the case, and if statements went out from the committee which could be challenged successfully there would be grit in the wheels of the movement. As one who had been in intimate contact with the poor, and had observed closely the conditions in which they lived, he felt that the fact could not be denied that in very many poor homes the money available for food was not expended in the best way. The dietetic ruts in which a large proportion of the population moved were simply appalling. He had been trying as far as he could to bring this matter of nutrition down to practical politics, and he had shown that it was possible to obtain 350 calories for one penny and fifteen grams of protein for one penny. Much could be done by proper instruction of the working class in food purchase and preparation.

Dr. Nash's remarks were warmly criticized by various members of the audience, one of whom said that this was a policy of not trying to get rid of malnutrition, but of making the best of it, and he added that if the poor were given the money they would feed themselves a great deal better than the rich. Several women school teachers told pathetic stories of the undernourishment of their pupils, and pleaded for a more abundant and better organized provision of school meals.

Mr. LE GROS CLARK, the bureau secretary of the committee, stated that it was the desire of the committee to get out not only scientific bulletins on the question of food, but also bulletins on the powers of local authorities in these respects, and he suggested that local groups be organized to study the question in their own district and to bring to the attention of the local authorities the need for free school feeding for families of unemployed workers, the provision of free milk at clinics, meals at nursery schools, and scales of relief adequate to supply full nourishment.

PRAISE AND DISPRAISE OF DOCTORS

DR. HUTCHISON'S MACALISTER LECTURE

The eighth annual lecture in memory of Sir John Macalister, for many years secretary and librarian of the Royal Society of Medicine, was delivered at the National Temperance Hospital, on June 21st, by Dr. Robert Hutchison, the incoming president of the society. His subject was "Praise and Dispraise of Doctors," and included a very large number of quotations from non-medical writers, ancient and modern, on the subject of the medical profession. We understand that the quotations were chosen from a considerable number collected by Dr. Gladys Wauchope and the lecturer, which are being published in the *London Hospital Gazette* as a medical anthology.

Dr. Hutchison began by glancing at popular proverbs, a collection of which, bearing on the medical profession, was published many years ago in the *British Medical Journal*.¹ The following were examples: "He who has killed a thousand persons is half a doctor" (Tamil proverb); "When you call the physician, call the judge to make your will" (German); "The doctor is often more to be feared than the disease" (French); "If the doctor cures, the eye sees it; if he kills, the earth hides it." (Scottish and Portuguese). Dr. Hutchison also quoted one French and Italian saying, "A surgeon should be young; a physician old," which he thought might be considered when fixing the retiring age for medical and surgical members of a hospital staff! One proverb ran: "A young physician makes a lumpy churchyard." The most sweeping condemnation was a saying in the Talmud: "The best of doctors is ripe for hell." Dr. Hutchison said that he had some hope that this referred to doctors of law, but he was assured, on Jewish authority, that it referred to doctors of medicine.

CLASSICAL WRITERS OF ANTIQUITY

In the Scriptures there were few references to medicine, though everyone knew the well-known panegyric of Jesus the son of Sirach, in Ecclesiasticus; also the poignant verse in St. Mark's Gospel about the woman with an issue of blood who "had suffered many things of many physicians, and had spent all that she had, and was nothing better, but rather worse"—an oblique condemnation of the profession which might well be pondered, Dr. Hutchison thought, by the gynaecologists.

Turning to the classical writers, there was a handsome compliment in Homer:

"A wise physician skilled our wounds to heal,
Is more than armies to the public's weal."

Aescop's fables, however, were disparaging, and Heraclitus went so far as to say that, "doctors excepted, there was no one more stupid than the grammarians." Menander made a shrewd hit when he said that "a prattling physician is another disease to the sick man." Mimmermos, in the seventh century B.C., had an interesting comment on prognosis: "There are doctors who to show their worth and to be sure of an excuse make the bad

seem worse, and of the worse make a disaster." Plato made the curious remark that doctors "had better not be in robust health, and should have had all manner of diseases in their own persons."

Roman writers were more bitter in their comments than the Greeks, probably because in the early Empire most of the physicians in Rome were Greeks, whom the Romans despised. The elder Pliny, in his *Natural History*, had some very derogatory remarks to make, among them the following: "The art of physic hath this peculiar gift and privilege alone, that whosoever professeth himself a physician is straightways believed, say what he will, and yet to speak the truth, there are no lies dearer sold or more dangerous than those which proceed out of a physician's mouth." Pliny was severe on the extreme avarice of doctors, and referred to the "merchandise, spoil, and havoc" that they make when they see their patients in danger of death. Jovenal exercised his wit at the expense of the profession; Quintilian had no faith in doctors and regarded medicine as only serving to keep us hopeful; while Plotinus, in the second century A.D., denounced medicine as "the chief of errors."

THE MIDDLE AGES

Coming to mediaeval writers, Dr. Hutchison mentioned the portrait by Chaucer of the doctor in the Prologue to the *Canterbury Tales*. The chief features of the doctor were apparently his belief in astrology, his knowledge of classical and Arabian authors, his spare but nourishing and digestible diet, his indifference to the Bible, his fine dress, and his love of money. From John of Salisbury, who lived two centuries earlier than Chaucer, the lecturer quoted at length: "When I hear them [theoretical physicians] talk I fancy that they can raise the dead, and are in no way inferior to either Aesculapius or Mercury. And yet with all my admiration I am much troubled at one matter, and that is that they are so singularly at variance in their discussions and in the opinions which are drawn from them." This twelfth century schoolman continued: "Perhaps you look for me to say what the common people say, that the physicians are a class of people who kill every man in the most polite and courteous manner. Well, you will be disappointed. God forbid that I should do them this injury." The most violent mediaeval opponent of medicine, however, was Petrarch, who devoted four books of invectives to the medical profession. One of his letters to the Pope, which Dr. Hutchison quoted at length, ended as follows: "... shun the physician who is eminent not for his knowledge but solely for his powers of speech, as you would a lurking assassin or a poisoner"—reminding one of Osler's dictum that there were only two kinds of doctors, those who practised with their brains and those who practised with their tongues.

RENAISSANCE WRITERS

The Renaissance writers, too, found the profession a butt for their wit, though Erasmus, perhaps because he was a friend of Linacre, was complimentary, pointing out that "the theologian makes men repent of their sins, but it is owing to the doctor that there is anyone to repent," and he endorsed the view of antiquity that "no reward worthy enough can be paid to the skill and trust of the worthy doctor." Savonarola, too, was kind: "Love teacheth him [the physician] everything, and will be the measure and rule of all the measures and rules of medicine." Montaigne, on the other hand, repeated the old gibe that doctors do not practise what they preach, tying their patients to "a strict diet of panada [a soaked and sweetened bread] or a syrup, while feeding themselves upon a melon, dainty fruits, much good meat, and all manner of good wine." To this period, also, belonged the

¹ *British Medical Journal*, 1911, ii, 1482.

delightful and oft-quoted Latin epigram attributed to Euricius Cordus:

"Three faces the physician hath;
First as an angel he,
When he is sought; next when he helps,
A god he seems to be;
And last of all, when he has made
The sick, diseased, well
And asks his guerdon then he seems
A very fiend of hell."

Shakespeare took a more sympathetic attitude than most of the Elizabethan dramatists, who were abusive of the profession. Here the lecturer referred to the recent collection of their references by Mr. Macleod Yearsley, in *Doctors in Elizabethan Drama*. Thomas Dekker, though abusive in his plays, gave, in his heart-rending account of the plague of London, one of the most beautiful metaphors about the doctor ever penned: "A good physician comes to thee in the shape of an angel, and therefore let him boldly take thee by the hand, for he has been in God's garden, gathering herbs, and sovereign roots to cure thee. The good physician deals in simples and will be simply honest with thee in thy preservation." The lecturer selected for quotation three well-known criticisms by Francis Bacon in his *Advancement of Learning*. One read: "Physicians are some of them so pleasing and conformable to the humour of the patient as they press not the true cure of the disease."

THE DAWN OF MODERN MEDICINE

By the seventeenth century, with the dawn of modern medicine, criticism became graver and more serious, and there was greater disposition to acknowledge the virtues of the doctor and to excuse his failings, though dispraise was still commoner than praise. A sympathetic picture was given by Thomas Fuller, the author of *The Worthies of England*. One of his sayings was that to poor people the good physician "prescribes cheap but wholesome medicine, not removing the consumption out of their bodies into their purses." It was Fuller who wished for surgeons the three requisites of their practice—an eagle's eye, a lady's hand, and a lion's heart. Molière, of all seventeenth century writers, was the most satirical at the expense of doctors, but his plays did not lend themselves well to brief quotation, and Dr. Hutchison refrained from any examples.

Eighteenth century physicians and surgeons laid themselves open to attack by their frequent pomposity and pedantry in that age of full-bottomed wigs, snuff-boxes, and gold-headed canes. Voltaire defined a physician as "one who pours drugs of which he knows little into a body of which he knows less." It was the same French cynic who declared that the art of war was "like medicine, murderous and conjectural." Horace Walpole abhorred physicians, and declared that by "quack" he meant an impostor not in opposition to but in common with physicians. On the other hand, Pope, who was not overgiven to commendation, said of physicians that they were, in general, the most amiable companions and the best friends, as well as the most learned men he knew. Much praise came from Samuel Johnson, who said that doctors did more good to mankind without a prospect of reward than any profession of men whatever. Addison, in the *Spectator*, said that "when a nation abounds in physicians it grows thin of people." On the other hand, in the *Tatler* he—or it might have been Steele—said that there was not a more useful man in the commonwealth than a good physician. Blackstone of the *Commentaries* declared that the medical profession beyond all others remarkably deserved the character of general and extensive knowledge. Samuel Parr thought that of the three learned professions, in erudition, in science, and in habits of deep and comprehensive thinking,

the pre-eminence must be assigned in some degree to physicians. Henry Fielding, the novelist, made a hit when he said that "every physician almost hath his favourite disease," and Swift, that "no man values the best medicine if administered by a physician whose person he hates and despises." Hannah More wondered why people should be so fond of the company of their physician till she recollected that he was the only person with whom one dared to talk continually of oneself, without interruption, contradiction, or censure.

OLD GIBES NOW OUTWORN

Many of the old gibes at doctors had lost their point by the nineteenth century, and were only repeated, if at all, in jest. Among modern writers praise was commoner than criticism, and criticism was reserved more for the manners and customs of the profession as a whole than for its practice or morals. Scott gave a charming picture of a country surgeon in Gideon Gray. Dickens, who reserved his criticisms for the law, had very little to say about medicine (but had Dr. Hutchison forgotten Bob Sawyer?). Thackeray had a few favourable though patronizing references in his *Book of Snobs*, and George Eliot, in *Middlemarch*, depicted with great skill and humour different types of practitioners, but refrained from general praise and blame, except when she said that it was seldom a medical man had true religious views—there was too much pride of intellect.

Dr. Hutchison quoted some opinions by politicians, including Lord Salisbury's "Doctors are a social cement," and Mr. Lloyd George's statement that while he was dealing with the Insurance Act he found doctors "unreasonable and unruly." Ruskin paid a graceful tribute in *Crown of Wild Olives*, "... if they are good doctors, and the choice were fairly put to them they would rather cure their patient and lose their fee than kill him and get it." A number of other *obiter dicta* by various writers, from Sydney Smith to Dean Inge, were quoted, the following from Sydney Smith, "The sixth commandment is suspended by one medical diploma from the North of England to the South," and this from E. F. Benson, "Doctors are the only autocrats we have left." Robert Louis Stevenson's remark was also quoted:

"He [the physician] is the flower, such as it is, of our civilization; and when that stage of man is done with, and only remembered to be marvelled at in history, he will be thought to have shared as little as any in the defects of the period and most notably exhibited the virtues of the race. Generosity he has, such as is possible to those who practise an art, never to those who drive a trade; discretion, tested by a hundred secrets; tact, tried in a thousand embarrassments; and, what are more important, Heraclean cheerfulness and courage."

It would appear, said Dr. Hutchison in conclusion, that praise and dispraise pretty well cancelled out, just as in individual practice undeserved blame was balanced by unearned credit. In the earlier periods of medicine blame was probably often well merited, but as the profession had risen in efficiency, so it had gained in esteem. Even now, however, it was probably true to say that the individual doctor was better liked than the profession as a whole.

The number of anti-tuberculous vaccinations by oral administration of B.C.G. vaccine (according to H. Mallard, *Bull. de l'Acad. de Méd.*, May 8th, 1934) has increased in the Côte d'Or Department from 443 cases in 1930 to 867 in 1933. Of these, 151 were notified by tuberculosis dispensaries, 397 by medical practitioners, and 319 by midwives. During the first year after birth the percentage mortality was 30 among non-vaccinated infants exposed to infection, as compared with 11 among vaccinated infants similarly exposed, and 8.5 among all infants.

HELP FOR THE DEAF

[THE BRITISH MEDICAL JOURNAL 1173

Many have been the discussions as to what disability constitutes the greatest handicap and deprivation in life—blindness, deafness, maiming, or crippling. What ever be the supreme evil, there is no doubt in the minds of medical men and women about the gravity of the loss sustained by those who cannot hear. Until recent times, however, little has been done to relieve the distress suffered by many deaf persons. Ample provision has been made for the blind, but the deaf have been in truth the Cinderellas of the philanthropic world. That omission is in the way of being remedied, largely through the activities of the National Institute for the Deaf, of which Lord Charnwood is the president. The Institute was founded in the year 1911, on the lines of the successful National Institute for the Blind, by the late Mr. Leo Bonn. In 1923 there was a most forward in its work, and in the following year a most useful handbook was published giving in compact form all the available information about the organizations furthering the interests of the deaf existing in the country. A new edition of this work has now been issued under the title *All About The Deaf. How the deaf are helped and how they may help themselves*.¹ It is an attempt, and an entirely successful attempt, to bring together information on every branch of the great problem of defective hearing. It does not deal with the strictly medical aspects of deafness, nor in a direct way with prevention; its object is to furnish practical help to those immediately concerned in looking after their fellow creatures who are deaf, from birth, from childhood, or in later years, and who need guidance, training, or assistance. It is intended to advance the welfare of a class whose affliction involves exceptional hardships and difficulties which in general are too little realized by those who enjoy the blessings of hearing.

But the book has its preventive aspect: by thus placing the problems of the deaf before social workers it is hoped that the information given about one large section of the deaf—namely, those known as the deafened—will accomplish much in awakening the public mind to the gravity of lost hearing and to the need for effort to prevent this calamity, as well as the importance of assisting those who suffer in this way to surmount the difficulties created by the partial or complete absence of audible communication with their fellows. The problem is no small one. It is calculated that some 40,000 persons in Great Britain have been deaf from birth or from very early life; but the tale of the deafened is unknown. Besides the mass of well-indexed particulars concerning schools, institutes,

homes, and hospitals, *All About The Deaf* includes a couple of short papers on the "Prevention of Deafness," by Dr. Kerr Love and Dr. Arthur G. Wells, which are informative. These have now been republished by the National Institute in a sixpenny pamphlet for popular use, with a table of hints to parents, and an appendix giving the recommendations on the public provisions required to prevent deafness which were drawn up by the medical committee of the Institute in October, 1933. The handbook as a whole will be of great value to school medical officers. A copy ought to have its place upon the shelves of every medical reference library.

BRITISH POST-GRADUATE MEDICAL SCHOOL

The Senate of the University of London, acting on recommendations by the Governing Body, has now filled three of the four university chairs tenable at the British Post-Graduate Medical School; and the new school, if all goes well, should open at Hammersmith before the end of this year. Professor Francis R. Fraser, physician and director of the medical professorial clinic at St. Bartholomew's, is appointed to the chair of medicine. Dr. James Young, gynaecologist to the Edinburgh Royal Infirmary and university lecturer in clinical obstetrics and gynaecology, is appointed to the chair of obstetrics and gynaecology. Professor E. H. Kettle, who has held the university professorship of pathology at St. Bartholomew's since 1927, is appointed to the chair of pathology. The chair of surgery has yet to be filled. In the *British Medical Journal* of March 17th (p. 487) we published an article by the dean of the post-graduate school, Dr. M. H. MacKeith, who comes to London from Oxford, giving an account of the origin of the scheme and the progress so far made with it; this included a general note on the lay-out of the group of buildings at Ducane Road, Hammersmith, and an indication of teaching arrangements and policy. The occupants of the new university chairs will be appointed by the London County Council to the visiting staff of the adjoining and associated hospital, of which Sir Carey Evans is medical superintendent. The four chairs, and their clinical obligations, are whole-time posts, and the professors may not hold any other public appointments nor engage in other professional work without the approval of the Governing Body. In the organization of the work of his department each professor will have a first assistant to act as chief of staff and executive officer. The choice of persons for these posts will no doubt be the next step taken in building up the teaching teams.

We may recall that the British Post-Graduate Medical School, after a pre-natal period of over ten years, was incorporated by Royal Charter in 1931 and that the Governing Body includes a representative (Sir Robert Bolam) of the British Medical Association. Its

¹ *All About The Deaf*. A revised edition of *The Problem of the Deaf*, 1923. London: The National Institute for the Deaf, 2, Bloomsbury Street, London, W.C.2. 1934. (3s., post free 3s. 3d.)

² *The Prevention of Deafness*. N.I.D. Booklets, No. 1. (6d.)

first chairman, the late Lord Chelmsford, has been succeeded by Sir Austen Chamberlain, who takes a warm interest in the project. The foundation stone of the new buildings was laid by the Chancellor of the Exchequer, Mr. Neville Chamberlain, in July, 1933, when the probable date for the opening of the school for the reception of students was announced as October, 1934. There appears, however, to be some doubt whether the machine will be ready to function as soon as that, and we note that the dates for two of the three appointments to chairs are officially minuted by the University of London: "from October 1st, 1934, or as soon thereafter as may be practicable." Meanwhile, the new post-graduate teaching institution has been admitted as a school of the university for a period of two years in the first place, permanent recognition being deferred for the present by reason of certain requirements of the university statutes which cannot be fulfilled until the actual date of opening.

SKELETAL DEFECTS OF ANIMALS

Comparative medicine as a research instrument is becoming of increasing importance to our profession, and its value in elucidating many medical problems now receives more and more recognition, if only because so much experimental work must be carried out on lower animals. A good example of this is seen in three lectures delivered by Sir Arnold Theiler at the Royal Veterinary College, under the auspices of the University of London, and published in the April and May issues of the *Veterinary Journal*. Sir Arnold was for many years director of the Veterinary Research Laboratories in South Africa, and is well known as an authority on deficiency diseases, especially those caused by lack of phosphorus and calcium. His lectures on the osteodystrophic diseases of domesticated animals are thus worthy of careful attention by workers in the field of human medicine. Diseases of bones have always been important to veterinary surgeons, particularly in the days of horse traffic, but the interest was mainly clinical, and conceptions of what their names stood for varied widely. Too often names used in human pathology were applied to conditions in animals on the basis of gross clinical or macroscopic similarity, and once the name of the disease had been taken over most of the ideas of causation accompanied it, without enough scrutiny of the evidence available for alternative explanations. Many of these explanations have only recently been forthcoming—largely as the outcome of Sir Arnold Theiler's own work—and their practical bearing is important.

All defective bone formation in domestic animals is now proved to be dietetic in origin, though dietary factors are not always the only factors concerned in the aetiology of these diseases. They result from a withdrawal of calcium phosphate from the whole skeleton, and this leads inevitably to pathological changes in the bones. Such changes vary with species, age, and mode of life. The normal functioning of the

mineral metabolism of the body depends upon the harmonious interaction of three dietary ingredients—vitamin D, calcium, phosphorus—but the absence of any one of these does not produce the same effect in all animals. Some species react more readily to one deficiency than to another, while in other species the same individual may react in two separate ways at the same time; different pictures appear to result from identical causes, and the same picture may be presented by diseases of unlike aetiology. Rickets and osteomalacia—using the terms in the strict pathological-anatomical sense—exist in sheep and cattle, apparently in pure form without complications. They also occur in pure form in pigs, but are sometimes associated with osteodystrophia fibrosa, a disease which can, however, appear independently. These diseases are also seen in dogs, though rickets and osteomalacia are more frequent, while in horses and goats osteodystrophia fibrosa is the common bone affection. Moreover, though osteodystrophia malacia (rickets and osteomalacia) is pathologically the same in the various domesticated animals, aetiotogically it is different in the different species, being primarily a deficiency of phosphorus in sheep and cattle, of calcium in pigs, and of vitamin D in dogs. True osteomalacia does not occur in horses, the condition generally called equine osteomalacia being really an osteodystrophia fibrosa (equivalent to Recklinghausen's osteitis fibrosa) caused by excess of phosphorus in relation to inadequate calcium. Curiously enough, such a failure of balance does not produce the condition in cattle, and it appears to be practically unknown in these animals.

The researches of Sir Arnold Theiler and his colleagues in South Africa have been of enormous economic importance, but their merit does not lie in that alone: they are a valuable contribution to comparative medicine, both by enabling a strict scientific comparison of the various bony disorders to be made, and by directing attention to the different courses which similar diseases may take in different species of animals.

STAPHYLOCOCCAL INFECTIONS IN DIABETES

Having discovered that in a large number of diabetic patients a staphylococcal factor was present in most cases of infection of the upper respiratory tract, J. A. Gilchrist and Mary J. Wilson¹ started to treat these cases with staphylococcal toxoid, and obtained very encouraging results, even though the weather conditions were adverse, cloud and rain prevailing. They also found themselves able to substitute various daily doses of insulin by a weekly injection of toxoid, and in all cases reduction of the insulin dose proved to be practicable. They refer to the discovery of Mills that there is a high diabetic rate north of the fiftieth parallel of latitude, and that the incidence of this disease is greatest in places where the climate is most changeable and stimulating. They are now convinced that in most of the sufferers from diabetes mellitus in the Toronto area

¹ *Canadian Med. Assoc. Journ.*, April, 1934, p. 353.

there is a staphylococcal factor, and that the administration of toxoid attacks the cause. The objection to antitoxin is the severity of the symptoms which may follow its employment in diabetics. Because of unpleasantly severe reactions in the earlier injections of toxoid they now start with half the usual dose, and dilute it with normal saline solution, the time of injection being chosen so that the uncomfortable stage is got over during sleep. The dizziness which may ensue is attributed to a low blood sugar level; it is relieved by eating, care being taken to give protein as well as carbohydrate. The authors invite further testing of their conclusions by others who have the care of diabetics in rainy seasons. They believe that the occurrence of such focal infections has been often overlooked in the past owing to inadequate examination of the sinuses, infection of which, they add, conduces to depression and even suicidal tendencies in diabetics. They argue that staphylococcal toxoid reduces the toxæmia which is producing diabetic hyperglycaemia, and increases the basal metabolic rate. It renders normal any morbid conditions of the haemoglobin and the non-protein nitrogen of the blood, permitting the discontinuance of iron administration in the secondary anaemias.

PRINCIPLES OF CHILD GUIDANCE

The fifth annual report of the Liverpool Child Guidance Council and Clinic, which deals with the year 1933, contains a lucid discussion of the diagnosis and correction of disorders of behaviour in children and adolescents. Dr. Dingwall Fordyce, honorary director of the clinic, points out that the only wise or safe approach to such work is under immediate medical direction—a timely caution in an age that is prone to make light of the difficulties while appreciating more and more the possibilities of the psychological aspects of education. Further, while the value of clinic advice and assistance is now well established, unnecessary resort to it is to be deprecated. Any measure tending to diminish self-confidence in the mind of the general public, such as, for example, unwise propaganda in the lay press, is harmful to the general purpose of the work. To these three principles Dr. Fordyce adds a fourth, insisting that, while an important function of the clinic is educative, this should in the main be fulfilled through efficient practical work and contacts. In the Liverpool Clinic, as elsewhere, the need for team work is recognized. All possible data are collected concerning the child's physical, emotional, and mental make-up, as well as the nature of the environment; these are then pooled and considered from different aspects by a body of observers. Since its inauguration over 350 children and adolescents have been dealt with; at the beginning of 1933 there were seventy cases under treatment, and during the year 124 new patients were admitted, fourteen being of pre-school age, ninety-nine of elementary school age, and eleven above school age. Inquiry into the origin of disordered behaviour showed that personal factors were twice as common as environmental. In older children the most frequent cause was traceable to the home environment, this exercising an adverse influence in thirty-three out of fifty-five cases, being the sole

factor in six cases and the predominant one in twelve others. As would be expected, the apportioning of the causation is more complex in these older children, the environment embracing home, school, and clinic, while an investigation of the individual character has to take into account the physique, the emotional and intellectual components, and any psychopathy. The commonest difficulty in the first seven years of life was found to be uncontrollable outbursts of temper, usually associated with lax or inconsistent parental handling, and often curable by advice to those responsible. Dr. Muriel Barton Hall emphasizes the gratifying results that follow individual psychiatric treatment of the younger children. She remarks: "Experience of treating patients in middle and later life suffering from gross forms of nervous and mental disorder, developments of the uncorrected—even unexpressed—fears, dreads, and doubts that tortured their childhood, illustrates the vital importance of rectifying these problems during early years, a time when they may be dealt with and banished with comparative ease." In regard to the older children Dr. F. Hopkins notes that the great majority pass through adolescence in a perfectly normal and uneventful way. "There is no reason why, with good health and sensible upbringing, they should not. There are, however, greater dangers at this period for those children who are temperamentally susceptible, or whose upbringing has been injudicious. The realization of this would do much to prevent or mitigate the distress that does so frequently occur." Looking ahead, Dr. Fordyce contends that child guidance is a branch of paediatrics, and should therefore be most successfully conducted as a special line of work associated with a children's hospital, provided it retains all facilities for handling cases referred by public authorities and social agencies when no private practitioner is in charge of the child. So will the clinical and educational facilities of child guidance be turned to best advantage.

VITAMIN A DEFICIENCY

In the current issue of the *Archives of Disease in Childhood* Dr. Helen Mackay concludes the study of vitamin A deficiency in children with the results of her own investigation into skin lesions and their prophylaxis by this vitamin. Her previous summary of the literature and composite picture of a child suffering from vitamin A deficiency referred to in these columns¹ led her to conclude that one of the earliest stages of disease due to absence of sufficient of this vitamin from the diet of young children was an increased susceptibility to infections of the skin. Her own investigations confirm this view. Between January, 1931, and October, 1932, two groups of artificially fed babies were kept under observation in the out-patient department of the Queen's Hospital for Children. The average period of attendance was eight months. All the children were fed on a roller-process dried milk containing iron and ammonium citrate (hemolac), to which were added vitamin D, orange juice, and sugar. From the age of 7 to 8 months, solid food (including eggs, fish, vegetables, and meat) replaced part of the milk ration. Approximately half the children, sixty

¹ *British Medical Journal*, May 5th, 1934, p. 811.

in all, received in addition extra vitamin A, while the other half (fifty-eight children) were dependent for this vitamin upon that naturally present in their dried milk or in the mixed diet in the later months. The exact difference in the vitamin A intake in the two groups was difficult to compute, but it is safe to assume that the "treated" group received many times more. The groups were compared as regards weight and general morbidity rates, the number of illnesses being assessed for each child and for the groups as a whole. It is clear from the results, which have been statistically checked by Dr. Bradford Hill, that the addition of vitamin A had no influence on the general health, on rate of gain in weight, or on the general resistance to infection, whether to infections of the respiratory or digestive tract or to specific fevers. On the other hand, while the incidence of infections of the skin not due to microbial infection, such as urticaria, rough face, and sweat rash or erythema, was identical in the two groups, the incidence of "infective" lesions was, in the group receiving extra vitamin A, approximately half that of the control group. The lesions classed as "infective" may for the most part be regarded as due to some form of local irritation with an infection by local organisms of low virulence taking root as a result, and these include sore buttocks, sore scrotal skin, intertrigo, dribbling eruptions, etc. This difference is not only present for the groups as a whole throughout the period of investigation, but is also present in each of the four seasons under consideration, and is the only difference between the two groups which was uniform over the seasons. It seems to be proved by this work that slight deficiency in vitamin A may be a not uncommon condition among children attending the out-patient department of a hospital in the East End of London. The diet of the control group was by general standards a good one except for the omission of cod-liver oil, and one of Dr. Mackay's conclusions is that in the present state of our knowledge cod- or other fish-liver oil known to be potent in vitamins A and D is probably the most economical supplement for providing these factors, and should be a routine addition to the diet of all children of the type here under investigation.

THE WATER SITUATION

In many parts of the country the water situation gives rise to growing anxiety, and the need to safeguard supplies is at least as great as ever. There has been no such prolonged shortage of rain within living memory. In opening a reservoir at Bridgwater last week-end the Minister of Health said as plainly as he could that recent showers have not made it any less necessary for people to save water. Local authorities, in addition to what they are already doing to relieve the present scarcity, should plan ahead for difficulties foreseeable in August and September. Measures that can be taken are the sinking of new bores and wells, and the enlargement of wells, obtaining emergency supplies from neighbours, chlorinating impure supplies to make them serviceable, and distributing by cartage. County councils can help district councils with the services of experienced men. The Ministry and its water engineers have been helping the rural districts to deal

with the emergency. Measures are in progress which secure that rural authorities shall take action forthwith, and be prepared with plans for any further action necessary as the summer goes on. These authorities should make prompt use of all means and sources of help available in overcoming their difficulties. They should also press forward with their plans and applications for help for permanent water schemes out of the million pounds now available. When the emergency is over, as Sir Hilton Young said on June 22nd, it will be necessary to review the experience gained and consider the measures which it suggests. He will not anticipate the result of that review, but he can see some obvious common sense in the opinion held by practical men that the idea of a "grid" has little, if any, application to water supply. "Water has to be got where nature puts it, and of its own accord will only go where nature allows it to go. Its supply is conditioned by natural circumstances, such as watersheds. To disregard those conditions, as the idea of a grid suggests, would mean impossible cost in mains, tunnels, and pumps." In his view the key word for water supplies is not "nationalize," but "rationalize"; areas of supply being so reorganized as to bring them into closer relation with the facts of nature.

KING JAMES I

Dr. F. William Cock, who is well known for his encyclopaedic knowledge of medical lore, contributes to the *University College Hospital Magazine* (January-April, 1934) an account of the last illness and post-mortem examination of James I of England. He has translated the difficult Latin in which the original is written with the skill of a scholar, has added some useful notes, and illustrates his paper with a reproduction of one of the two portraits of the King in the Apothecaries' Hall, with a facsimile of a page of the funeral book in the Public Record Office, and with a reproduction of Scharff's drawing of the interior of the vault of Henry VII in Westminster Abbey showing James I's leaden coffin. "The account of the last illness and death with a summary of the pathological causes of the most renowned James, King of Great Britain of pious memory our very gracious Lord who, on the 27th Day of March 1625, by the compassion of God left this mortal and troublesome life" was perhaps dictated by Theodore Mayerne to Dr. David Bethune, a Scotsman and one of the Royal physicians. It deals rather hardly with the King as a man from his physician's point of view. It begins:

"It is true that the most serene King was gifted by Nature with an excellent constitution, but as age came on it was obvious that this was impoverished chiefly by errors in diet and by external causes. . . . His stomach by its want of tone was many times distended by wind and its movements hindered by symptoms of imperfect digestion so manifest that he was continually drinking strong wine to give himself ease. To this weakness of the body must be added many errors of diet, for although moderate enough in ordinary food, because he was edentulous he never masticated it but bolted it whole. Moreover in the matter of garden fruit he grossly exceeded, greedily eating it at any time day or night. Again in drinking he was shockingly intemperate, mixing his liquor so that at any one time he took ale, beer, sherry and sweet white French or Greek wine, which were his favourite and customary beverages even when

they were rosy and full of lees. From these habits it followed that evil humours were bred in him."

The King suffered from piles as well as feebleness in his kidneys, which were frequently obstructed by calculi and gravel. He was also troubled by uneasy sleep and gouty pains. He suffered much from constipation, which ought to have been relieved by purgatives,

"but Nature happily intervened removing this huge load, for the King was entirely set against these and every other kind of medical help. It is more than certain that unless a benevolent Nature had often helped His Majesty by attacks of profuse diarrhoea with an enormous excretion of foul liquid motions his strength would have failed under such a burden."

He was attacked on March 4th by what at first was unanimously described as a fever of the intermittent tertian variety. During the first few days the paroxysms of fever followed by sweating were comparatively slight, but the King was a bad patient, for neither at the beginning of a fit would he leave off drinking, nor in the fever stage could he put up with the heavy uneasiness, nor as the sweating stage declined would he suffer any other method of treatment, but again drank deeply, and would listen to nothing about the use of helpful remedies. Everything he did was in a most restless way. "And so the King of all Monarchs the most Christian, upright and prudent, most piously left this earthly prison on March 27th, 1625." On the following day the body was opened. The internal parts were very carefully inspected and their appearance accurately noted. In the light of modern morbid anatomy the results were inconclusive, and Dr. Cock asks at the end of his interesting essay, "What did James I die of?" It cost £2,000 to bury him.

A PLAY ABOUT DOCTORS

A French player told the dramatic critic of the *Times* the other day that from an actor's point of view a British audience was the best in the world. "I dismissed the saying as an habitual compliment. But the verdict was repeated and repeated again: the English come to enjoy themselves; the French to sit in judgement. Perhaps it is true." We think so; and in proof thereof London playgoers without too keen an eye for probability are finding entertainment now at the Strand Theatre in the performances of *Living Dangerously*. The authors, Mr. Reginald Simpson and Mr. Frank Gregory, have slipped up here and there on technical matters, but not enough to mar the pleasure of a doctor's evening off duty, and they are well served by the principal actors in a balanced cast. Mr. Godfrey Tearle is good as the good doctor who, after his name has been struck off the *Medical Register* on a trumped-up charge, makes a fresh start in America with the lady who shared his ordeal. And Mr. Martin Walker is good as the very bad doctor. This horrid person indulges in illicit drug traffic for gain, suborns his secretary-mistress, offers his wife to his partner (her medical attendant), and then brings a false accusation against him to the General Medical Council. After an interval of eleven years he blackmails the former partner in New York, but comes to grief through mixing villainy with whisky when the occasion calls for steadiness of head and hand. The trial scene in the Council

Chamber is moving, and there can be very few people who know enough to feel sure that such things don't really happen quite like that. It may shock us a little to hear the president (Mr. Allan Aynsworth) giving so much latitude to complainant's counsel; but a plot is a plot, and our emotions are there to be worked upon. The result is a brisk parlour-melodrama and a deft piece of propaganda for the right of appeal from penal decisions of the G.M.C.

RESEARCH IN BACTERIAL CHEMISTRY

The Medical Research Council announces the inauguration of new arrangements for further combined chemical and bacteriological studies of the conditions which govern the life and multiplication of micro-organisms causing disease. These have been made possible by the co-operation of the Middlesex Hospital Medical School, the trustees of the late Viscount Leverhulme, and the Sir Halley Stewart Trust. Accommodation and facilities are being provided at the Middlesex Hospital in the Bland-Sutton Institute of Pathology and the adjoining Courtauld Institute of Biochemistry. The investigations will be directed by Dr. Paul Fildes, F.R.S., who has been appointed a member of the scientific staff of the Medical Research Council. The other workers are Mr. B. C. J. G. Knight, with a Halley Stewart Research Scholarship, and Dr. G. P. Gladstone and Dr. G. Maxwell Richardson, holding Leverhulme Research Fellowships. The arrangements took effect on June 1st, and the support given by the co-operating bodies will suffice for an initial period of five years.

PREVENTION OF BLINDNESS

At a meeting of the executive committee of the International Association for the Prevention of Blindness, held in Paris last month, Professor de Lapersonne (the chairman) gave a brief account of the work accomplished during 1933. In the course of the proceedings Dr. Park Lewis, on behalf of the American Ophthalmological Society and other bodies, presented the Dana Medal to Professor de Lapersonne for his distinguished services in ophthalmology and in the prevention of blindness. It was decided that Mr. Bishop Harman should be consulted on the choice of date and place of meeting for the next general assembly of the association in 1935.

ANNUAL REPRESENTATIVE MEETING

The thirty-second annual meeting of the Representative Body of the British Medical Association will be held in the Grand Hall, Town Hall, Bournemouth, commencing at 9.30 a.m. on Friday, July 20th. All duly appointed Representatives and members of the Central Council for 1933-4, and those already elected to the Council for 1934-5, are entitled to take part in the proceedings. Cards of admission, agenda, and relevant documents will be posted from the Head Office on July 12th.

The Asiatic Society of Bengal has awarded the Barclay Memorial Medal for 1934 to Professor R. Row, M.D., D.Sc., of Bombay, for conspicuously meritorious contributions to biological science, with special reference to India.

LISTER INSTITUTE REPORT

The fortieth annual report of the Lister Institute of Preventive Medicine, dated May 30th, 1934, contains the customary review of the scientific work carried out there during the year. In the introduction, the Governing Body records its appreciation of the continued co-operation of the Medical Research Council, and states that the hospitality of the Institute's laboratories has been extended to two foreign guests displaced from scientific posts in Germany—Professor Ellinger of Düsseldorf and Miss Klieneberger of Frankfurt. As regards the national collection of type cultures 200 new types were deposited for maintenance in the collection, while over 5,000 cultures of bacteria and fungi were distributed to workers at home and abroad. A revised list of the fungi in the collection is being prepared for publication in the *Transactions of the British Mycological Society*. A list of scientific papers published from the Lister Institute appears at the end of the report, together with the balance sheet and accounts. Below we give a summary of those pages of the report which deal with the research work undertaken during the year.

VIRUS STUDIES

Vaccinia.—Dr. G. H. Eagles, using a kidney extract culture medium, has completed a series of passages in which the washed elementary bodies from dermal virus used for initial seeding gave rise to seven generations of subculture without apparent loss of potency. The final subculture represented a 20th multiplication of the original potency. Dr. C. R. Amies has used suspensions of elementary bodies (which represent the virus in its purest form) for vaccination against small-pox: these suspensions retain their activity for several weeks at room temperature, and the loss of activity at 0°C. is small. Dr. Amies has also attempted to confirm a claim by Russian workers that vaccinia virus can be cultivated *in vitro* in symbiosis with yeasts. The experiments have not, however, been successful.

Varicella and Herpes.—Following up previous work on varicella Dr. Amies has confirmed the finding of elementary bodies in herpes zoster, and has obtained pure suspensions of them from the vesicle fluid. Suspensions are agglutinated by convalescent serum, which also agglutinates the elementary bodies of varicella to approximately the same titre. In a few cases varicella convalescent serum has agglutinated both varicella and zoster elementary bodies. There thus seems to be support for the belief that the two viruses, if not identical, are closely related.

Other Viruses.—Dr. M. H. Finkelstein has been studying the relationship of fowl-pox and pigeon-pox, while Mr. D. W. Henderson has had successful results with the growth of louping-ill virus *in vitro*. Dr. Sabin has been investigating a virus recovered from a fatal case of human acute ascending myelitis ("B" virus) from the point of view of a possible relationship to the herpetic group of viruses. This virus is readily communicable to rabbits, in which an ascending paralysis regularly follows an intradermal injection: in the form of rabbit brain or cord it is exceedingly active. No convalescent rabbit serum for cross-immunity has been secured as yet. Experiments with this "B" virus show that rhesus monkeys can be immunized by intracutaneous and intraperitoneal inoculation. Mice are also susceptible to the "B" virus, which is filterable through Berkefeld V and N candles, the centrifuged filtrate yielding a highly potent sediment. Further studies have been made on the virus of pleuropneumonia and agalactia.

SEROLOGICAL STUDIES

Dr. H. L. Schütze has been studying the development, stability, and antigenic importance of the heat-labile envelopes of *B. pestis*. It seems that the antigen content in the envelope is sensitive to alkali, and that if the vaccine is neutralized before sterilization the envelope

substance retains a greater antigenic power. Miss D. Steabben has been investigating the antigenic condition of Shiga's dysentery bacillus, and finds that the preparation of a vaccine incubated at 45° C. contains 50 per cent. more bacterial substance than the 37° C. vaccine, and between four and five times more toxin.

Amongst the spore-bearing anaerobes *C. oedematis maligni* has been subjected to cross-immunization experiments with the "O" antigen, while work commenced last year on the antibacterial mechanisms associated with *C. tetani* has been continued. Experiments with the high titre antitoxin sera against *C. tetani* spore infection have shown that such sera only delay the onset of the disease, which later ends fatally. Repeated intravenous inoculation of antitoxin may, however, induce a successful result. As regards the relation of virulence and susceptibility to "O" antigen it has now been found by Dr. A. Felix and Miss R. M. Pitt that highly agglutinable strains of *B. typhosus* are of low virulence, while non-agglutinable strains are highly virulent. The virulent strains are without demonstrable capsule, though the results do not contradict the view that "rough" forms are non-virulent, but indicate that the presence of smooth "O" antigen does not completely define virulence.

ENDOCRINOLOGY

The biological assay of testicular hormone has been continued in experiments showing the physiological variations from the average of the weights of organs in rats. Injections of the hormone in oil gave satisfactory results in assay, suggesting that this (and probably other dissolved substances) is absorbed from oily solutions during the whole period of injection at some constant rate. Castration experiments have shown that effects are noticeable not only in the sexual organs but also in several other organs. Castration produces striking atrophy of the secondary sexual organs (prostate, seminal vesicles, penis, and preputial glands), slight atrophy of the thyroid, and, later, of the liver and kidneys, involution of the thymus being delayed, and the adrenals and hypophysis being hypertrophied. There is an increase in fat deposition, and a slight decrease in heart weight is also specific. The specificity of the changes produced is supported by results of hormone injection into castrated male rats, the injection causing a return towards the normal.

Other work connected with hormones includes experiments performed to show the effect on the sexual, endocrine, and other organs, of adrenalectomy, and of cortical extract injection into normal and castrated rats. The latter experiments reveal no influence of the cortical extract on either the weight or histological structure of the organs mentioned in either normal or castrated rats. On the subject of vitamins, recent experiments show that vitamin E deficiency produces changes similar to those produced by vitamin A.

RESEARCH ON NUTRITION

Vitamin Standards.—During the last three years the Institute has devoted much time to points connected with the standards adopted at the international conference in 1931. The following subjects have been investigated. Vitamin A: pure crystalline carotene as standard; influence on stability of temperature and of solvent used; the relative value of various methods of vitamin A estimation. Vitamin B: the stability at different temperatures of the standard absorption product on acid fullers' earth from rice polishings. Vitamin C: suitability of raw ascorbic acid as standard in place of fresh lemon juice previously recommended.

The biological value of carotene as a source of vitamin A has been tested, together with its efficacy in different solvents: coco-nut oil has already been found to be the most satisfactory for use with crystalline carotene, and several samples of the oil have been compared. It has been found that the same sample of carotene dissolved in different oils will not always have the same biological value. A comparison has also been made between the different forms of carotene. Dissolved in the same sample

of coco-nut oil β -carotene has a deep yellow colour, and is biologically active in smaller doses than in the sample used as international standard. As to vitamin D, examination of plant material for this substance has been continued; results have been irregular, however, though it has been established that the vitamin which is abundantly formed when fresh green leaves are exposed to powerful ultra-violet light irradiation tends to disappear when the material is kept. No evidence was obtained of the presence of vitamin D in germinated wheat, contrary to statements of some workers that cereals develop vitamin D as well as vitamin C during germination.

Biological Value of Proteins.—Dr. Harriette Chick and Mr. J. C. D. Hutchinson have been investigating the balance-sheet method of studying the nutritive value of proteins, and the latter has done some work on the relative value of wheat and maize produce in the nutrition of young rats. The work offers another argument against the theory which would explain the association of endemic pellagra with the use of diets containing as the staple cereal maize products by an amino-acid deficiency in such diets.

Vitamin C and Ascorbic Acid.—It was pointed out in the last report that a number of specimens of ascorbic acid and its derivatives were examined for antiscorbutic activity with a view to establishing whether vitamin C was identical with the acid. Evidence has accumulated that synthetic l-ascorbic acid is active and that this compound possesses antiscorbutic activity *per se*. The reversibly oxidized form of this acid has been the subject of tests for its detection, but so far there has been little success. Work has also proceeded on the physiological functions of vitamin C and its content in germinated peas, fresh fruit, and canned apples, while Dr. Gough has been examining a number of suprarenal glands from human necropsies by the silver nitrate method, and has succeeded in showing (in collaboration with Dr. Zilva) a high degree of antiscorbutic activity in the pituitary as well as the suprarenals.

BIOCHEMISTRY

Alcoholic fermentation has been the subject of sundry investigations, and further knowledge has been gained of the reactions involving phosphoric acid during the breakdown of sugars by the enzyme-complex of yeast. The mechanism of calcification in animal tissues has been further studied by Professor Robison, whose work suggests that the two mechanisms of calcification may together form a complex enzyme system analogous to those of muscle and yeast. The chemical nature of the oxytocic hormone of the posterior pituitary gland has again been the subject of study by Dr. Gulland. He has confirmed the dual nature of the interaction with nitrous acid, and has also shown that there is a third concurrent inactivation in which the hormone is attacked by nitric acid produced by aerial oxidation of the nitrous acid during the experiments. Other subjects of study in this group include the action of chemical substances on cells, the constitution of nucleic acids, and oxidation experiments bearing on the metabolism of fat.

THERAPEUTIC SERUM

Recent work has thrown light on the nature of a purpurogenic toxin in connexion with the pneumococcus, and Drs. Petrie and Morgan are endeavouring to obtain by selective breeding genetically pure lines of this toxin which are respectively susceptible and resistant to the purpura-producing toxin, and to compare the survival rates when equivalent doses of virulent test-culture are given to mice.

A fresh attempt has been made to simplify the preparation of the toxin and antitoxin of *B. welchii*, and the results have been so satisfactory that the present methods can now be regarded as purely routine. It is believed that the preparation of the specific toxin and antitoxin from *V. septique* will offer no special difficulty.

As regards the recent work by Panton and others at the London Hospital on the use of a specific antitoxin in acute and subacute staphylococcal infections, and of a toxoid preparation in the treatment of the chronic type of in-

fection, the department is co-operating with the Wellcome Physiological Research Laboratories in supplying the specific remedies for clinical tests which are being organized by the Therapeutic Trials Committee of the Medical Research Council.

Convalescent serum for poliomyelitis is being sent to the Western Fever Hospital, where early cases of the disease are admitted, while a new supply of serum from immunized horses has been found to possess very high virus-neutralizing value in tests on monkeys. It is available for prophylactic use in contacts.

Other subjects of study under the therapeutic section have been: titration of anti-dysentery serum, biochemical investigations into the specific substances of the meningococcus, and colorimetric methods for the estimation of glucosamine and N-acetylglucosamine. Finally, Dr. McClean and Dr. Favilli are collaborating in further experiments on the nature of local immunity explained on the basis of a lowered permeability of the tissues, and Dr. Lumsden has again been given facilities for his work on an anticancer serum by immunization of sheep.

HEALTH OF SCOTLAND

DEPARTMENT'S ANNUAL REPORT

The fifth annual report of the Department of Health for Scotland,¹ recording its main administrative activities for the year 1933, is now available. The report draws attention to the necessity for taking a broad view of the probable industrial developments of any locality before determining the suitable sites for additional houses and the future uses of cleared areas, and this question will be reviewed when the programmes of local authorities for the five years 1934-8 come under scrutiny. With regard to the national health policy, a review of the various health services appeared necessary, and is now being carried out by the Departmental Committee on Scottish Health Services, the terms of reference being "To review the existing health services of Scotland in the light of modern conditions of knowledge, and to make recommendations on any changes in policy and organization that may be considered necessary for the promotion of efficiency and economy." The volume of certified sickness among the insured population continued to be high, amounting in the year up to June 30th, 1933, to 19,000,000 days, accounted for by about 400,000 separate cases of illness. Out of every 1,000 insured persons there were 227 cases of illness.

HOUSING

The output of houses under State-aided schemes was considerably accelerated during the year. The number built was 20,915; this constituted a record since the national housing effort began in 1919, and was almost double the output for the year 1931. The total number of houses completed since 1919 up to the end of 1933 was 164,740. The output of houses by private enterprise without State assistance was 5,570, which also constituted a record since 1919. Progress has been made in slum clearance, and at the end of the year tenders had been approved for the erection of 21,266 houses by 150 local authorities. Of these houses, 10,847 have been completed. The subsidies payable to local authorities under the various Housing Acts came under review at the end of the year, and it was decided to continue unaltered until October, 1936, the subsidy for slum clearance; but, in accordance with the Government's policy of leaving ordinary house building to unassisted private enterprise, it was decided that no subsidy would be payable for such houses completed after March 31st, 1934. In rural areas 2,815 dwellings were reconditioned during the year. A total capital expenditure of approximately £9,500,000 had been determined by the Department at the end of 1933 in respect of 197 housing schemes, and a capital expenditure of £896,000 in respect of twenty-four slum clearance schemes.

¹ Cmd. 4599. H.M. Stationery Office, 129, George Street, Edinburgh. (2s. net.)

GENERAL SANITATION

The year 1933 may be regarded as one of exceptional drought, though this did not necessarily involve a shortage of water supplies. Information called for by the Department in January, 1934, showed that in sixty burghs out of a total of 195 there had been some shortage during the year. In landward areas, 106 special water supply districts out of 404 had also been short of water. In the counties of Aberdeen and Kincardine trouble was experienced with some rural water supplies which exhibited dangerous plumbo-solvency. The danger was first brought to light by a case of lead poisoning in Aberdeen Infirmary, in which the illness was traced to the water supply. A number of sources were subsequently found to be affected, especially wells distributed widely over moorland districts. The plumbo-solvency was obviously due to peat acids. Three wells were treated experimentally with limestone chippings to neutralize the acid, and this treatment reduced the plumbo-solvency to a safe figure. Many wells in the two counties were afterwards similarly treated with satisfactory results. With regard to public cleansing, it was found that in many rural districts accumulations of refuse still existed. The question of village scavenging, however, has received increased attention during recent years, and mechanical traction has been the prime factor in this development. Amalgamation of districts has been tried with satisfactory results, and the collection of refuse over a large area by mechanical traction has given good results. The importance of the provision of suitable receptacles for the storage of refuse is emphasized, because it appears that any type of container devoid of covering and incapable of retaining liquid refuse is in many places considered good enough. This is regarded as one of the worst features of public cleansing, and the Department urges local authorities to make by-laws regulating the size and capacity of ashbins.

FOOD SUPPLIES

Reference is made in the report to an investigation by Drs. Leighton and M'Kinlay upon the average amount of liquid milk consumed in Scottish households (*British Medical Journal*, April 28th, 1934, p. 769). This showed that for Scotland as a whole the consumption was 0.48 pint per head per day, and it is recommended that this might be increased with great benefit to the public health. The Department continued to press local authorities to replace part-time veterinary inspectors of dairy cattle by inspectors not engaged in private practice in the area of the authority. The need for veterinary inspection of dairy cattle in exempted premises was again evident from the fact that in several instances cottagers' cows were found to be suffering from clinical tuberculosis. Representations were made to the Department by producers of milk from graded tubercle-free herds and by local authorities that the retail prices fixed by the Milk Marketing Board for certified and Grade A (T.T.) milk were too high; this situation is receiving attention. The progress in the production of tubercle-free milk is indicated by the fact that the number of herds licensed in recent years increased from forty-four in 1927 to 103 in 1932 for certified milk, and from fifty to 103 in the same period for Grade A (T.T.) milk. There are at least 115 other tubercle-free herds in the country, although their owners have hesitated to bring them under the grading system owing to the limited demand for tubercle-free milk. The report suggests that a substantially increased demand would do more than any other single measure for the eradication of tuberculosis from dairy herds. Reports by veterinary inspectors show that there is a continued improvement in the cleanliness of cows and byres, and in the methods of milk production generally, due largely to the educative influences of local authorities' inspectors. The practice of certain dairy associations of paying a bonus to producers with the least bacterial content of milk samples has also proved effective in raising the standard of milk production. In Edinburgh a test has been carried out with the object of detecting *Brucella abortus*; in 256

samples examined 17.5 per cent. were found to show this organism. A high standard of meat inspection and control of slaughterhouses under the Meat Regulations (Scotland), 1932, was maintained during the year, and several convictions were obtained for infringement of the regulations—for example, for the removal of organs to conceal traces of tuberculosis. Further amendments of the regulations are at present under consideration. Two small outbreaks of food poisoning occurred during the year: one in Glasgow, where the suspected foodstuff was a sausage; and one in West Lothian, where the illness was attributed to the consumption of cheap pork.

MATERNITY AND CHILD HEALTH SERVICES

The year 1933 has shown a new low record in the birth rate, which was 17.6 per 1,000 of the population. There has also been a decline in the infantile mortality to 81 per 1,000 births as against 86 for 1932 and an average of 85 for the preceding five years. The maternal mortality rate also declined to 5.9 per 1,000 births as compared with 6.3 for 1932 and 6.6 for the preceding five years. Data collected by the Department's Scientific Advisory Committee concerning all births in Scotland over a period of six months are at present being analysed, and a report on maternal mortality and morbidity will shortly be available. Infant mortality in 47.7 per cent. of cases was due to congenital causes; in 19.9 per cent. to bronchitis and pneumonia; in 10.3 per cent. to diarrhoea; and in 5.2 per cent. to whooping-cough. The number of children between the ages of 1 and 5 in Scotland was estimated to be 330,900, and the number of deaths in this group was 2,638, representing a death rate of 8 per 1,000 of the age group as compared with a rate of 10.1 in 1932. The chief causes of death were bronchitis and pneumonia in 28.5 per cent. and whooping-cough in 14.3 per cent. Deaths of children between 5 and 15 numbered 1,740 in 1933 as compared with 1,827 in 1932. The chief causes of death in this group were tuberculosis, 268 cases; violence, 263; diphtheria, 180; and pneumonia, 128. Proposals for additional maternity beds have been made to the Department during the year from local authorities of Kirkcaldy, Dunfermline, Renfrewshire, Motherwell, Kilmarnock, Ayrshire, and Greenock. An experimental reorganization of the medical inspection of school children has been made in Edinburgh. Under the new scheme, which was in operation during the year 1932-3, medical inspection of entrants and leavers has been continued, but instead of the inspection of an intermediate age group, an annual classroom survey of all children in the schools has been made. The advantages of this have been an earlier detection of defects with medical supervision at an earlier stage of disability; an examination of the child in its usual school environment; and closer contact in the classroom between teacher and medical officer. With regard to maternal welfare, there were 187 maternity and child welfare centres in Scotland at which arrangements were made for giving advice to expectant mothers. The number of first attendances at ante-natal clinics has risen from 9,103 in 1925 to 29,099 in 1932. It is stated that 49 per cent. of the births in Scotland during 1932 were attended by doctors, 29 per cent. by midwives, and 22 per cent. were institutional. The number of maternity beds at the end of 1933 was 459 provided by local authorities and 513 in voluntary hospitals. There has been a steadily increasing tendency in recent years towards institutional treatment in childbirth. Concerning child welfare the report states that about 86 per cent. of the children born in Scotland during 1932 were visited by health visitors, who made an average of over six visits to each child during the year. The number of children between the ages of 1 and 5 visited by health visitors during the year 1932 was 99,372 as against 82,509 in the preceding year, while the number brought to welfare centres was 19,478 as compared with 18,769. With regard to the school child, the number of schools under inspection in 1933 was 3,364 with a total of 827,311 children on the registers. The number of children medically examined in selected age groups was 243,345, and in addition 148,975 children were referred to medical officers for special

examination, and 89,670 children found defective at previous examinations were re-examined. The chief defects were: decayed teeth, with one to four decayed in 57.4 per cent., and five or more decayed in 13.5 per cent.; enlargement of lymphatic glands in 20 per cent. of cases; enlarged tonsils in 17.7 per cent.; nutrition below the average in 5.7 per cent.; external eye diseases in 5.2 per cent.; nasal catarrh in 4.5 per cent.; poor vision in 4.4 per cent.; and infective skin conditions in 2.8 per cent.

[To be concluded]

Ireland

Conditions and Pay in the Public Health Service

The Minister for Local Government and Public Health of the Irish Free State, Mr. S. T. O'Kelly, who was accompanied by the Parliamentary Secretary, Dr. C. Ward, Mr. E. P. McCarroll, and Dr. R. P. McDonnell, received a deputation recently from the executive of the Irish Medical Committee, consisting of Drs. R. J. Rowlette, J. P. Shanley, P. O'Dowd, T. P. MacDonnell, and T. Hennessy, and Mr. T. M. Gick. The Minister agreed that the salaries of medical officers were on the small side in certain areas (the deputation had made special reference to the Health Boards of South Tipperary and of Counties Roscommon, Leitrim, and Longford). Representations would, he said, be made to the Health Boards mentioned to reconsider the salaries. He also promised to inquire into the salaries advertised for the dispensary districts in Cashel, Golden, Tipperary, and Cappagh, and to try to arrange a more reasonable remuneration for the post of whole-time medical officer of health to the borough of Waterford. In the case of the salaries in mental hospitals the Minister was prepared to consider any claim submitted to him. The sum of £30 per annum, plus rates and taxes, was, he considered, a reasonable and fair rent for dispensary houses. The deputation pointed out that medical officers as tenants were at a great disadvantage, since the fixity of tenure, etc., of dispensary houses, provided by the Town Tenants Acts, did not apply to them, with the result that, on retirement, they and their families were homeless, although they might have paid in rent the total cost of building the house. With regard to promotion in the medical services, the Minister said he was anxious there should be provision for this in all deserving cases, and he would consider the best means of giving effect to it. The medical attention of those school children who usually receive treatment under the Medical Charities Acts was discussed, and the Minister expressed the hope that in a very short time there would be a whole-time county medical officer of health for the outstanding counties and chief boroughs in the Free State. Concerning the practice of some health boards of undertaking the treatment of the children of well-to-do parents and applying the money towards lessening the expense of the county scheme, the Department would take steps to prevent such irregularities in all cases brought to its notice. The fee for immunization against diphtheria was, he considered, a matter for arrangement between the local authorities and the medical profession. The question of fees for the remuneration for registrars of births, deaths, and marriages was being considered with a view to improvement. In the case of extra medical benefits provided by approved societies—for example, in respect of glasses—the Minister was entirely in favour of the proposal that ophthalmic surgeons should be employed instead of opticians. The whole question of the remuneration for anaesthetics and the differentiation between major and minor operations was to be considered, as also was the matter concerning the reinstatement of Dr. H. V. McKeogh. The issue of red tickets in midwifery cases to the dispensary doctor,

and, in the circumstances, his position, and that of the midwife who receives no ticket, was discussed; it was pointed out that the regulations at present in force made the doctor responsible for the case, but that he could seek subsequent relief from attendance in normal cases by arranging for a midwife. A recent order issued by the County Wexford Health Board directing that dispensary doctors should report all puerperal cases in which the patient had a continuous increased temperature for twenty-four hours was considered by the deputation to be *ultra vires*, since the medical attendant alone was responsible for the diagnosis: the Minister promised to have the matter put in order. The principle of the advisability of consulting accredited medical representatives when changes were about to be made in remuneration, and in administrative and other regulations, was approved. Fees for vaccination and vaccination certificates were considered to be statutory, and to require legislation to remedy any inadequacy. The Minister said that the allocation of hospitals in South Tipperary was engaging his attention.

Centralization of Fever Hospitals in Dublin

The Dublin County Council has decided to approve the scheme of the Free State Hospital Commission for the concentration of fever treatment in a central hospital controlled by a board of management. The latter would be representative of the public bodies previously responsible for providing adequate fever treatment, and of the Cork Street Fever Hospital Board. The Commission attaches special importance to the value of public representation on the board of management. A tentative figure of seventeen members has been fixed, and it is proposed that the representation should be as follows: Dublin Corporation, seven; Dublin County Council, three; and Cork Street Hospital, seven. It is also proposed to invite the principal medical bodies to associate themselves in an advisory capacity with the board of management by nominating representatives. The building of the hospital would be borne by sweepstakes funds, and the accommodation to be provided would be a matter for discussion between the Commission of the City and county medical officers of health. A measure of agreement has been reached between the Commission and the Cork Street authorities, by which the latter will contribute towards the upkeep of the new hospital. The Commission's proposals have now to be submitted to the Minister for Local Government and Public Health.

National Health Insurance

In the Dáil, on the estimate for national health insurance, Mr. S. T. O'Kelly stated that the increase in State grant was due to the additional expenditure on benefits and to the greater number of contributions which it was estimated would be paid in 1934. There had been a steady increase in the annual contribution income of the National Health Insurance Fund, which in 1933 was calculated to have reached £602,000. The expenditure on benefits, however, also increased, and in 1933 it was estimated to be £760,969. The average number of persons in receipt of benefits weekly through the year was 26,000. Complaints of insured persons concerning their treatment by approved societies numbered about 120 a week only, or one dissatisfied claimant out of over 220. During the eleven months ended February, 1934, sums totalling over £400 were recovered for injured persons from employers in respect of benefits lost through neglect to pay contributions. The number of medical certificates issued in 1933 was 1,338,828. The accumulated funds forming the assets of the national health insurance amounted to £3,551,780 at the end of 1933, an increase of £50,390. The annual income derived from dividends and interest was £125,970.

Scotland

Proposed Public Medical Service for Edinburgh

A meeting of general practitioners in the city of Edinburgh was held in the British Medical Association Scottish House on June 28th, at 8.30 p.m., to consider a draft scheme for the formation of a public medical service for the area covered by the city of Edinburgh. The scheme has been drawn up on the lines of the model scheme issued by the Association to provide medical attendance and medicine for the dependants of insured persons and others of similar means. It is proposed that any registered medical practitioner within the area may become a member of the service on payment of an entry fee of £2 2s.; that the affairs of the service should be managed by a committee consisting of a chairman, honorary secretary, and treasurer, with twelve other members elected from the medical profession; and that medical service and medicines should be provided for subscribers after acceptance by the practitioner of their choice at an entrance fee of one shilling and a subscription per week varying from fourpence for one subscriber up to one shilling for a family of four or more. The services to be provided under the scheme will approximate as closely as possible to those given to persons insured under the National Health Insurance Scheme.

New Glasgow Professor

The vacancy in the Muirhead Chair of Medicine at Glasgow University, caused by the approaching retirement of Professor Walter K. Hunter, M.D., D.Sc., has been filled by the appointment of Dr. Archibald Wilson Harrington. Dr. Harrington, who takes up duty on October 1st next, is 56 years of age and has been one of the physicians to Glasgow Royal Infirmary since 1926. He graduated M.B., Ch.B. Glasg. in 1900 and M.D. in 1903, and became a Fellow of the Royal Faculty of Physicians and Surgeons in 1912. After holding resident posts in Glasgow Royal Infirmary, Royal Maternity Hospital and Glasgow Fever Hospital at Ruchill, he joined the Royal Infirmary staff in 1906 and became assistant physician in 1913. During the war he was a captain in the R.A.M.C. on the staff of the 3rd Scottish General Hospital, Glasgow, and in 1916 went to Salonika with the 38th General Hospital. Later he was in France as officer in charge of the Medical Division of the 58th General Hospital with the rank of major. After his return to Glasgow he became visiting physician to the Ministry of Pensions Hospital at Bellahouston in 1920, a post which he resigned on taking charge of wards in Glasgow Royal Infirmary in 1926. Dr. Harrington has also held the posts of consulting physician to the Glasgow Royal Maternity Hospital and to the Glasgow Royal Mental Hospital at Gartnavel.

Chiropody in Edinburgh

Lord Elphinstone was elected president of the Edinburgh Foot Clinic at the annual meeting, at which Professor John Fraser took the chair. Mr. Robert Stirling said that the number of treatments at the clinic during 1933 had totalled 13,633 as against 10,360 in 1932. There were thousands of men and women whose occupations involved long periods of standing, and whose foot troubles often interfered with their work; those people were beginning to look to chiropody for relief. Patients came to this clinic from all parts of Scotland. It was generally considered that the highest efficiency in any profession was found in the centre of training, and it was well to

recollect that attached to this foot clinic there was a school of chiropody. Students were trained for two years, and at the end of that period, if they passed their examinations, they received the diploma of the Incorporated Society of Chiropodists. This school had a wide reputation, and the clinic had always worked in harmony with the medical profession. Lord Elphinstone, in opening a new theatre, said that judging by the rapid development in the last ten years, the clinic would soon require to be open all day in order to cope with the demands made upon it. He appealed to the generosity of the public to support the clinic.

England and Wales

Tuberculosis Prevention

The thirty-fifth annual general meeting of members of the National Association for the Prevention of Tuberculosis was held in London on June 15th (an account of the conference appeared last week at page 1136). Sir Robert Philip presented the annual report, commenting on the gratifying facts that in twenty years the mortality rate in England from all forms of tuberculosis had fallen, approximately, 41 per cent., and in Scotland 50 per cent. He added that the death rate from this disease in 1932 was the lowest ever recorded in this country, and showed a substantial reduction over the 1931 figure. The rate of decline was accelerating. In co-operation with the Scottish branch of the British Red Cross Society, the Royal Victoria Hospital Tuberculosis Trust, and the Scottish branch of the Queen's Institute of District Nursing, the National Association had carried out a highly significant mission of investigation and instruction through the Highlands and Islands of Scotland. It was hoped, soon, to appoint a nurse commissioner for tuberculosis in East Suffolk, a new step which might be the precursor of a more general movement of this kind throughout the country. The disused Empire Marketing Board poster frames would be utilized in part for propaganda against tuberculosis. The Burrow Hill Sanatorium Colony for youths between the ages of 14 and 18 was obtaining subsequent employment for a gratifying percentage of these patients. Thanks to the special appeal of 1926-8 the financial position of the National Association was good, but there were many demands for fresh, useful expenditure. Lady Titchfield, who had been prominently associated with this appeal, and had been elected vice-chairman of the council, gave a short account of the Christmas seal scheme. Apparently first thought of in Australia in 1897, it had later occurred to a Danish postal clerk, in 1904, that money for charitable purposes could be raised by issuing special stamps or seals for Christmas letters and parcels. Since then the Danish mail had carried these stamps every Christmas, and most other civilized countries had taken up the scheme. Last year it had been adopted in this country by the National Association, and would be continued. Lady Titchfield stressed the point that the money accruing was devoted to the local anti-tuberculosis work in the places where the seals were sold, and thus served to stimulate interest and attract support. In connexion with this conference, visits were paid to Colindale and High Wood Hospitals and King George V and Pinewood Sanatoria. The conference hall housed a very attractive collection of exhibits, including specimens of work by members of handicraft classes organized by tuberculosis care committees, and a great variety of instructional and propaganda literature.

Baby Week, 1934

Many medical authorities will give their views on matters connected with the health of mothers, infants, and young children during the eighteenth National Baby Week, which is the occasion of the National Conference on Maternity and Child Welfare, organized by the National Association for the Prevention of Infant Mortality, to be held at Birmingham from July 3rd to 5th. Usually the conference takes place in London, but occasionally it has been held in provincial centres. The National Baby Week Council this year has focused attention upon the general subject of the making of an A1 nation, and directs particular attention to the problem of nutrition, as affecting the foundations of national health. The Council as an organization concerned with propaganda has devised a great variety of ways of stimulating the interest of young and old alike in this question of specific interest. One is the issue to midwives of a pamphlet on the diet of the expectant mother, written by Professor S. J. Cowell of St. Thomas's Hospital Medical School. It is being distributed to midwives through local supervising authorities, and copies may be had on application to the National Baby Week Council, 117, Piccadilly, London, W.1. Other events of next week bearing upon nutrition are essay-writing on nutrition for the family by domestic science students, and postcard competitions for school girls and boys. Girls are asked to write on six good rules they would bear in mind in preparing the family meals. Boys are asked to write six rules they would follow if they had gardens of their own and wished to use these gardens to help their mothers to feed the family all the year round. In another competition nursery nurses are invited to plan the meals of the 3-5-year-old child. All these activities should stimulate public interest in seeking to know the principles of good nutrition.

L.C.C. Dentists and Nurses

The London County Council is proposing that from July 1st the salaries of dentists at hospitals and institutions under the management of its Hospitals and Medical Services Committee shall be, for full-time, £500 a year, rising by annual increments of £25 to £650, and for part-time, £50 a year for one session of approximately two and a half hours a week for fifty-two weeks a year, and at the rate of £65 a year for each additional session of the same length for fifty-two weeks. All dentists must possess a degree or recognized diploma in dental surgery. The hours of duty for the full-time officers are to be thirty-three hours a week; travelling time from a central point in London to be included. The Council has also been reconsidering the supervisory nursing staff (that is, the various grades of sister) for its general hospitals. The present staffing is held to be inadequate, and the question of adding substantially to the number of sisters cannot longer be postponed. It is proposed to create 105 additional positions, which will ensure an adequate standard for normal requirements, but not sufficient to ensure that at each of the larger hospitals there will be one ward sister not normally allocated to a definite ward or other duties, but available to be drawn upon in case of emergency for duty at her own hospital or one of the smaller hospitals. The number of such emergencies in a large service calling temporarily for the services of a ward sister is considerable, and it is therefore proposed, in addition to the 105 allocated positions, to have twenty other new positions of ward sister, to be allocated normally to hospitals with a bed accommodation of 500 or over, but available for temporary transfer elsewhere when necessary. The new proposals will result in an additional expenditure of nearly £25,000 in the current financial year.

Bristol Sanitary Congress

Further details have now been received about the annual congress of the Royal Sanitary Institute at Bristol from July 9th to 14th. The congress is under the presidency of Dr. Stanley Badoek, Pro-Chancellor of the University of Bristol, who will deliver his inaugural address on the first afternoon. The Minister of Health will address a general session of the congress on the afternoon of July 13th on "Some Aspects of the Housing Question." In addition to independent meetings of the six Sections—namely, preventive medicine; engineering, architecture, and town planning; maternity, child welfare, and school hygiene; veterinary hygiene; national health insurance; and the hygiene of food—there will be conferences of the representatives of sanitary authorities, of medical officers of health, engineers and surveyors, sanitary inspectors, and health visitors. Among the topics to be discussed are: the water supply problem; administrative difficulties in municipal housing; posture and its relation to health; the eradication of bovine tuberculosis; the problem of the mental defective; the teaching of mothercraft; mental development of the child between the ages of 2 and 5; sickness experience and sickness expectancy; sanitation in modern architecture; and the avoidance and destruction of sewage odours. A discussion on nutrition and the public health will be opened by Professor J. A. Nixon, who will be followed by Professor R. H. A. Plimmer and Dr. H. E. Magee of the Ministry of Health. Further particulars of this congress can be obtained from the secretary of the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.1.

Reports of Societies

SURGERY OF THE SYMPATHETIC SYSTEM

At a meeting of the Aberdeen Medico-Chirurgical Society, on June 7th, with the president, Mr. ALEX. MITCHELL, in the chair, Professor J. R. LEARMONTH read a paper on "The Surgery of the Sympathetic Nervous System."

Professor Learmonth began by recalling that the efferent fibres of the sympathetic nerves left the spinal cord in its anterior roots, between the first thoracic and second lumbar segments, inclusive, and, detaching themselves from the spinal nerves in the white rami communicantes, they reached the great ganglionated paravertebral chains. These chains had two uses. They provided a shunting system whereby (a) a certain number of fibres were side-tracked for the supply of viscera, and (b) the remainder were returned (by the grey rami communicantes) to travel with the somatic nerves. By their extent (from base of skull to tip of coccyx) they compensated for the fact that not all the segments of the spinal cord gave off sympathetic fibres. The activity of those fibres that travelled with somatic nerves produced the following effects: (1) vaso-constriction of the arterial tree, and probably also of the capillaries; (2) increase in the secretion of sweat; (3) contraction of the unstriated muscle in the skin, which caused erection of the hairs and "goose-flesh." Interruption of these fibres was followed in the area so denervated by (1) vaso-dilatation, (2) absence of sweating, (3) absence of goose-flesh and of erection of hairs. These effects were produced by the liberation, at the endings of sympathetic nerves, of a substance apparently identical with adrenaline, to which Cannon had given the non-committal name of "sympathin." This substance was the link between nervous impulse on the one hand and its translation into changes of muscular and glandular activity on the other.

SYMPATHECTOMY TO SECURE VASO-DILATATION

Broadly speaking, sympathectomy would be of therapeutic value to secure vaso-dilatation in a part that needed more blood. No local evil effects followed the procedure;

the increase in warmth of the part from the access of additional blood was not an inconvenience, and the increased capacity of part of the arterial tree was not followed by a fall in systemic blood pressure. The operation was a satisfactory method of producing hyperaemia. To the question whether the local hyperaemia that followed sympathectomy was permanent, Professor Learmonth answered that, when the denervation was complete, and when local structural changes in the vessels were absent, the local increase in blood supply was permanent. Although a few sympathetic fibres reached the proximal segments of great arteries directly from neighbouring sympathetic ganglia, by far the greatest number reached the peripheral arterial system by being detached at intervals from the somatic nerves of the part. Hence the most effective sympathetic denervation of a part could be done by division or resection of the "bottle-neck" in which these vaso-constrictor fibres were concentrated—namely, the grey rami communicantes or their parents, the sympathetic chains. For the lower extremity this was a relatively easy matter; it was accomplished by the removal of the second, third, and fourth lumbar ganglia, and the part of the chain that connected these. It was much more difficult to ensure that all the vaso-constrictor fibres to the upper extremity had been severed, for their anatomical position made them less accessible, and their arrangement was less constant. The surgeon aimed at removing the sympathetic chain from the inferior cervical ganglion to the second thoracic ganglion, inclusive; but even this extensive procedure might fail to produce complete sympathetic denervation. Even after technically complete procedures evidence was accumulating (J. C. White) that the denervated muscle might still contract as a result of the liberation of excessive amounts of adrenaline during emotional crisis; such vaso-constriction was, of course, temporary.

With regard to the second postulate—normality, or near normality, of the vessels, especially the arteries—it was obvious that in pathological processes which led to narrowing of the arteries—for example, in thrombo-angiitis obliterans—if the disease progressed, a stage would be reached when the arterial system, however dilated originally, became inadequate for the supply of the limb. Even in Raynaud's disease, though in the early stages structural changes in the vessels were absent, in the later stages changes in the calibre of the vessels might make it impossible to secure permanent increase in the flow of blood. Because of these possible structural changes the surgeon, before carrying out a sympathectomy to secure vaso-dilatation, must satisfy himself that the peripheral arteries were capable of dilating. Thus it was necessary to have some method of producing and of measuring the amount of peripheral dilatation that was possible. For clinical purposes a sufficiently accurate method was to measure, by a thermocouple, the rise in surface temperature of an extremity when its vessels were dilated. For producing vaso-dilatation the most convenient method in the wards was to warm the body, with the exception of the limb or limbs to be tested, in a cabinet—for example, under an electric light cage. The vessels in the unwarmed parts dilated because of a sympathetic reflex. The maximum temperature that could be produced by complete paralysis of the regional vaso-constrictor nerves in a normal limb varied with the room temperature. When this was about 20° C. the "vaso-dilatation level" was about 32° C. Morton and Scott had found that if the thermometric readings did not reach at least 28° C. during the test sympathectomy was unlikely to be of benefit.

INDICATIONS FOR SYMPATHECTOMY

Professor Learmonth next discussed conditions in which sympathectomy might provide a permanently increased supply of blood in cases shown to be appropriate by the above tests. In suitably chosen cases sympathectomy would permanently relieve the symptoms, and banish the signs, of Raynaud's disease. The hands or feet became warm, and the areas of superficial gangrene healed with remarkable rapidity. The fairest indication of the success

of the operation was the almost uniform desire of patients on whom unilateral operation had been performed to have the other limb denervated. In the group of structural disease of the peripheral arteries he included arterio-sclerotic disease, thrombo-angiitis obliterans, syphilitic endarteritis, the late stages of Raynaud's disease, and certain cases of scleroderma. Patients afflicted with one or other of these diseases came under notice suffering from intermittent claudication, impending gangrene of the digits, or both these features. The operability rate in this group was low; one could hope to provide a remedy for the complaints only if greater volume of blood could be furnished to the limb, and/or facilitate its distribution to the areas requiring it. Distribution might be facilitated in two ways: (a) by producing vaso-dilatation in existing channels, a possibility dependent on the presence or absence of structural changes in the arterioles; (b) by leading to the opening up of new anastomotic channels. In the lecturer's experience sympathectomy was not worth while in arteriosclerotic disease; the age of the patient, the progressive nature of the lesion, and the lack of resilience in aged vessels all pointed to the desirability of a conservative attitude.

The widest field for operation was in thrombo-angiitis obliterans, the victims of which were comparatively young. They could be divided into three groups: (1) When the disease was rapidly progressive and surgery had nothing to offer. (2) Slowly progressive disease. If tests showed a satisfactory rise of temperature, sympathectomy might be advised. The resultant vaso-dilatation might "last out" the patient's lifetime, or it might defer the necessity for amputation. (3) When the disease reached a certain stage and then seemed to be arrested. In selected cases sympathectomy might avoid amputation and deal satisfactorily with local gangrenous areas.

A limb extensively paralysed as a result of anterior poliomyelitis was often cold, blue, and, especially in winter, subject to ulceration and chilblains. The vascular condition appeared to depend on two factors, of which the more important was poor venous return as a result of the absence of support afforded to veins by normal muscles, whether at rest or contracting. The second factor was hypoplasia of the main artery to the limb, which appeared to be proportionately greater than the loss of substance in the member. In spite of these unpromising pathological conditions the lecturer had been agreeably surprised at securing, by sympathectomy, a rise of surface temperature of about 5° C. in several such cases. The effect of this increase in blood supply on the nutrition of the skin had so far been satisfactory. In the treatment of intractable ulceration of the leg the increase of blood supply after sympathectomy was occasionally of use. His own experience included two types of case: (1) ulcers secondary to disease of the central nervous system, such as might complicate spina bifida, and (2) intractable varicose ulceration.

The operation had been performed also in cases of scleroderma, when the condition was distal and associated with gangrene; the immediate results were good. Sympathectomy had been employed, too, though perhaps less justifiably, in the treatment of hyperhidrosis. Finally, in certain cases of periarticular polyarthritis, in patients under 40, sympathectomy often relieved pain and improved the function of hands and feet.

VISCERAL SYMPATHECTOMY

The efferent sympathetic nerves to the viscera controlled their local blood supply; and in addition those destined for hollow muscular viscera might exercise their effects in two ways: (1) by leading to changes in the calibre of the viscus, and (2) by regulating its function of transmitting its contents. The immediate functions of the two sets of nerves that reached hollow viscera appeared to be twofold: (1) the sympathetic nerves were inhibitory to the musculature of hollow viscera and motor to their smooth sphincters, and (2) the parasympathetic nerves were motor to the musculature of hollow viscera and inhibitory to their sphincters. Operations had been devised for the

division of the sympathetic nerves of the lower urinary tract, of the distal part of the colon, and of the rectum; the roots of these nerves approached each other so closely that at the pelvic brim they were easily accessible immediately under the peritoneum, in the form of a single meshwork or strand, called the superior hypogastric plexus, or presacral nerve. The object of these operations had been to secure proper emptying of one of these organs, and only those cases were chosen in which organic obstruction was absent. From a functional point of view the hollow systems under consideration consisted of a series of reservoirs and conduits separated from each other, and ultimately from the exterior, by sphincter mechanisms of smooth muscle. The improper emptying of such a living system might be the result of many factors, acting singly or in combination. One of the great difficulties in assessing the relative importance of possible factors was the degree of autonomy possessed by many of the viscera when deprived of their extrinsic nerve supply; this physiological self-sufficiency was most marked in the alimentary tract. The simplest cause of failure-to-empty was paralysis of the musculature of a viscus. A second cause was incoordination of the contractions that were, attempting to convey material along the system. A third cause was sympathetic overactivity, of such a degree that inhibitory impulses overwhelmed motor impulses, so that the muscular tube remained relaxed, and formed a passive container. A fourth possible cause was resistance to the passage of the contents of a conduit offered by a sphincter of smooth muscle.

Among conditions that might be benefited by visceral sympathetomy Professor Learmonth mentioned Hirschsprung's disease. That improvement in emptying the bowel followed division of its sympathetic nerves was an incidental clinical observation made by Royle and Wade. The denervation could be performed by any one of several techniques. Any of these operations might be efficacious in securing unaided evacuation of the colon; but it was too early yet to dogmatize on the permanence of the results. Although the operation had been employed, and with occasional success, in cases of constipation that had resisted prolonged medical measures, its indiscriminate application was to be deprecated. It had this in its favour—that if its result fell short of complete success, except so far as sterility in the male was concerned, the patient was at least not any worse, and the continuity of the gut had not been altered. A third condition was paralysis of the ureters and bladders. A group of cases was met with in which great dilatation of the ureters, or of the ureters and bladder, occurred as a presumably congenital condition in the absence of demonstrable organic obstruction. These patients appeared to suffer from achalasia at the uretero-vesical juncture, the vesico-urethral juncture, or at both. Like Hirschsprung's disease, it yielded to sympathetic denervation of the ureters and bladder. Occasionally the internal sphincter of the bladder was alone affected by spasm or achalasia, and this condition had been relieved by division of its motor (sympathetic) nerves, even when "punch" operations had failed to bring relief. When the central origins of the motor (parasympathetic) nerves to the bladder had been damaged by injury or disease, it was sometimes possible to restore power-to-empty to the bladder by division of its sympathetic nerves in the presacral strand. This operation failed to afford relief when the lesion that led to paralysis of the vesical musculature was situated either in the hypogastric ganglia or in the wall of the bladder.

OPERATIONS FOR RELIEF OF PAIN

The operations so far enumerated had as their object the division of efferent sympathetic fibres. The system contained afferent nerves also, which mediated visceral reflexes and transmitted painful sensations from viscera. In the urinary and alimentary tracts the adequate stimuli for production of pain appeared to be limited to over-distension of a viscus, and spasmodic or incoordinated contraction of its musculature. The latter was the only type that might recur often enough to demand relief. Such recurring spasm was to be found in the painful contractions of a chronically inflamed bladder,

and in the painful uterine contractions at the menstrual periods. When operating for the relief of intractable somatic pain the surgeon attacked the final concentration of pain fibres in the spino-thalamic tract of the spinal cord. It appeared that fibres mediating visceral pain were not so thoroughly concentrated in the cord; they could be divided, with least fear of an incomplete result, as they traversed the sympathetic "bottle-necks" in the abdomen and thorax. The "bottle-neck" formed by the presacral nerve contained a proportion of sensory fibres from both uterus and bladder. Dysmenorrhoea of the spasmodic type that had resisted ordinary methods of treatment could often, perhaps usually, be abolished by division of the presacral nerve. A careful selection of cases was necessary, and particular care must be exercised to exclude cases of the congestive type. The improvement was not to be ascribed solely to division of afferent "pain" fibres; probably the neurectomy deprived the cervix uteri of some of its tone. Painful chronic cystitis was sometimes a legacy from tuberculosis of the kidney; at other times it followed chronic pyogenic infection. Considerable relief from the distress of painful frequency followed division of the presacral nerve; but in this group of cases the urinary bladder was often contracted and its capacity so reduced that frequency was inevitable.

Sensory nerves from the heart reached, ultimately, the rami communicantes of the first five thoracic nerves, and entered the cord with the posterior roots of these nerves; apparently the majority of cardiac sensory nerves inclined to the left side. A number of operations had been designed with the object of severing these nerves at various points in their course for the relief of angina pectoris. From his own experience, and from a study of reports by trustworthy clinicians, Professor Learmonth was not inclined to regard the suppression of pain in angina as undesirable. The difficulty of performing elaborate operations in patients already in a precarious condition had been surmounted by the method of paravertebral alcohol block of the upper five thoracic nerves on the left side. The results of this had been satisfactory in a considerable proportion of cases, and although the injections must be carefully performed by an operator who had familiarized himself with the technique, the risk to the patient was minimal.

In conclusion, the lecturer urged that in any case in which sympathetomy was considered the problem should be viewed as a whole, and that the operation be employed as only part of the treatment. Carefully performed, after thorough investigation of individual patients, and in the conditions he had described, it formed a valuable addition to the therapeutic armamentarium of surgery.

At the meeting of the Royal Society on June 21st a paper by Drs. P. A. Buxton and D. J. Lewis, on "Climate and Tsetse Flies: Laboratory Studies upon *Glossina submorsitans* and *tachinoides*," was communicated by Sir Guy Marshall. In this the authors recalled that the number of tsetse flies which could be captured under standard conditions rose and fell with the season, and that many of the species were sharply limited to particular types of vegetation. It was thought that the limits were climatic. The paper described a series of experiments in which adults and pupae were exposed to controlled conditions in the laboratory. The work gave an approximate knowledge of the limits of temperature and humidity which were favourable or unfavourable to the fly; it was found possible to delimit an approximate optimum at which the flies fed best, lived longest, and had the highest birth rate. Records of temperature and humidity were also made in the permanent haunts of the fly, and conditions in the dry and the wet season contrasted. Observations made in the laboratory and in the field supported one another satisfactorily, and, taken together, they should tend to give precision to the control of *Glossina*, which would probably be achieved by altering the vegetation and with it the micro-climate. At the meeting on June 28th Professor W. L. Bragg delivered the Bakerian Lecture on "The Structure of Alloys."

CORRESPONDENCE

Pregnancy Diagnosis

SIR.—Dr. J. M. Robson, in his lecture on "Pregnancy Diagnosis in Theory and Practice" (*Journal*, June 16th, p. 1063) states with reference to the Friedman test, in which adult female rabbits are used as the test animals instead of immature female mice, that "the rabbit never (or very rarely) ovulates spontaneously, and hence, if mature animals are segregated, they are suitable for the test." Later on he says: "Sometimes the ovaries of normal rabbits contain small blood spots . . . it may be difficult to decide whether the blood spot has arisen as a result of the injection or independently of it." In such cases he advises a second examination of the rabbit after a further interval of twenty-four hours to determine whether there is any alteration in the size of the blood spots.

I have employed the Friedman method in this department for the past two and a half years, and about 700 tests have been performed with it. In 439 rabbits the ovaries have been inspected by laparotomy before injecting the urine for diagnosis. On thirty-one occasions—that is, in 7 per cent. of cases—blood spots have been found at this preliminary laparotomy. In seven of these the blood spots were sufficiently fresh to resemble exactly the appearance obtained by the recent injection of urine of pregnancy, and one would not have hesitated to report a positive result had the rabbits been inspected only after the injection of the urine for diagnosis. In one of these seven cases the animal was a virgin rabbit which had been isolated for three months, the isolation commencing before the rabbit reached puberty. It is possible that the three false positive results which occurred in Dr. Robson's series of 145 cases (one in a definitely non-pregnant subject and two in cases of "delayed menstruation") were due to recent spontaneous ovulation or formation of blood follicles, and would not have occurred had he resorted to preliminary laparotomy.

Dr. Robson advocates concentrating the gonadotropic hormones by extraction with rectified spirit, since it was found at the Edinburgh Pregnancy Diagnosis Station that the injection of untreated urine did not give sufficiently satisfactory results. "This," he says, "may be due to the interval elapsing between the collection of the urine and its receipt for examination being longer than has been the case with other investigators." In twenty-nine cases of my series the urine has yielded a positive reaction after being kept at room temperature for a period longer than twenty-four hours. The exact intervals between voiding and injection in these cases are as follows:

Interval	Number of Cases
25½ hours	3
2 days	9
3 days	6
4 days	3
5 days	5
6 days	2
8 days	1 (weak positive)

It is well established that if the urine is kept in an ice-chest its gonadotropic potency persists for a long time, even, in some cases, up to two years. Thus, though no appreciable diminution of potency occurs during the first week after voiding the urine, all specimens in this laboratory are placed in the ice-chest shortly after receipt, so that should the test need to be repeated the urine is still available, and there is no necessity to demand a further specimen from the patient.

In a certain small number of female adult rabbits it has been found that the injection of urine of pregnancy does not produce a positive reaction. Consequently, in order to

detect such unreactive test animals, it is the practice in this laboratory to inject urine of pregnancy in all rabbits in which the urine for diagnosis has produced no changes in the ovaries. If, after this procedure, the ovaries still remain unchanged, the animal is discarded and the test repeated on another rabbit.

In a series of 203 clinically controlled cases, in which the technique which I outlined at the Annual Meeting of the British Medical Association in Dublin last year (*British Medical Journal*, 1933, ii, 306) has been employed—namely, a preliminary laparotomy and subsequent injection of urine of pregnancy when the urine for diagnosis has given a negative result—the results obtained have been 113 correct positive, eighty-nine correct negative, and one doubtful. In the case of the doubtful result the patient bled per vaginam in the third month of her pregnancy, the specimen of urine being collected six hours after the commencement of bleeding. This specimen gave a negative result. Three days later a dead ovum was found in the cervical canal. This case is considered as a false negative result. No false positive result has been obtained in this series, so that the error of the 203 cases is 0.5 per cent.

By eliminating the test animal completely as a source of error by the procedure indicated above, the test may be made even slightly more reliable than the original Aschheim-Zondek test, in which the variability of reaction of the immature mice to urine of pregnancy can only be controlled by using more than one animal for each test.—I am, etc.,

Physiological Laboratory, Guy's
Hospital, S.E., June 18th.

P. M. F. BISHOP.

Intracranial Injury in the Newborn

SIR.—I have read with much interest the paper by Dr. Moncrieff on hypertonic rectal saline for intracranial injury in the newborn in your issue of June 16th (p. 1063). There is one criticism I should like to make, which is concerned particularly with the footnote to his paper.

I have recently emphasized the fact that when cerebral oedema is present the intracranial pressure is considerably higher than the venous pressure. The cerebral oedema, therefore, which commonly accompanies severe head injuries must have a beneficial effect in limiting haemorrhage from torn cerebral veins and sinuses. This point is of particular importance in the cases Dr. Moncrieff is considering, as damage to venous sinuses is common in birth injuries.

The administration of hypertonic solutions by the rectum has a powerful effect in reducing intracranial pressure, and if used soon after injury may encourage bleeding into the subdural space. For this reason I think that it is inadvisable to use treatment such as Dr. Moncrieff suggests as a prophylactic measure in cases of difficult delivery, but to reserve the treatment for the type of case he describes in which the symptoms and signs of increased intracranial pressure are clearly present.—I am, etc.,

W. RITCHIE RUSSELL, M.D.,

Edinburgh, June 19th.

Ligature of the Innominate Artery

SIR.—Mr. H. S. Souttar's paper on ligature of the innominate artery (*Journal*, June 16th, p. 1066) is very interesting, especially from the point of view of the cerebral circulation, but his literature only dates to 1915.

In 1928 I reported a case of ligature of the innominate and common carotid arteries for a subclavian aneurysm, caused by a fracture of the clavicle (published in the *British Medical Journal*, 1929, ii, 49). Following the operation it was observed that the right side

of the head was pallid and obviously colder than the other side: this persisted for forty-eight hours. The circulation in the hand was defective for twenty-four hours only, due apparently to some collateral circulation having already been established. It appears that the influence on the circulation was only temporary, no further trouble having arisen, although it is now nearly six years since the operation. From the statistics it is clear that there is a lower mortality rate when the innominate and common carotid arteries are both tied than when the innominate alone is tied.

As to anaesthesia, I used gas and oxygen, and with an almost bursting aneurysm (it did rupture at the operation, and needed a good deal of digital pressure with one finger to occlude the sac) I doubt whether local anaesthesia would have sufficed. Again, with local anaesthesia, I can see the difficulty of using the common carotid artery as a tractor.—I am, etc.,

Grimsby, June 20th.

C. L. GRANVILLE CHAPMAN.

Classification of Mental Disorders

SIR,—In reply to Sir R. Armstrong-Jones's letter in your issue of June 16th, I would point out that the classification of mental disorders was adopted by the Royal Medico-Psychological Association in 1933, and published in the *Journal of Mental Science*.—I am, etc.,

Burghill, nr. Hereford, June 26th. G. W. T. H. FLEMING.

Avertin for Toxic Goitre Operations

SIR,—Mr. Geoffrey Keynes's article of May 12th on avertin narcosis in operations for toxic goitre is of great interest, and he is to be congratulated on his excellent results. This type of anaesthetic has been very successfully employed during the past twelve months at the Northern Hospital in our cases of toxic goitre, and, like Mr. Keynes, we have been greatly impressed by those cases in which the pulse rate actually fell during operation to a level lower than the pre-operative rate, and also by the absence of worries in connexion with the anaesthetic, both during and after operation. Our honorary anaesthetist, Dr. R. J. Minnitt, is responsible for the following pre-anaesthetic routine.

Permission of the relatives is obtained, but the patient is not aware that an operation in the immediate future is contemplated. For at least four days beforehand a hypodermic injection of sterile water is given at the same time the premedication will be given on the operation day. Two hours after this a glucose saline is administered per rectum and the patient told that this is routine treatment. During these four days the patient is weighed on two different occasions. Two hours before the operation is due to commence omnopon 1/3 grain and scopolamine 1/150 grain is given hypodermically. This dose is modified according to the size and weight of the patient, who is quite unaware that an operation is to be carried out. One hour later the avertin solution is prepared on the basis of 0.1 grain per kilo of the patient's body weight. After about fifteen minutes this is slowly run into the rectum by a tube and funnel, with the patient lying on the left side. The patient is then kept quiet, and within twenty minutes can be transferred from the ward to the operating theatre. A drop or two of castor oil is placed in each eye, and a bandage applied. The ears are lightly plugged with cotton-wool, and a face-mask is fixed in position with a Clauen retainer, so that gas and oxygen can be administered at any moment. In the cases where there is the slightest reaction when the incision is made gas and oxygen is commenced from a McKesson machine. Care is taken that no cyanosis is allowed, and for this purpose 25 per cent. oxygen and 75 per cent. nitrous oxide is generally required. This is sufficient to complete the narcosis if the avertin anaesthesia is satisfactory. Rebreathing is given throughout the operation.

Mr. Keynes commented on the result of preliminary ligation as a first-stage procedure. In our experience in bad cases it is not helpful and in mild cases it is unnecessary, and we consider it too liable to upset the patient to justify its use.

We do not think it wise to treat severe cases of toxic goitre in a general surgical ward, especially as several weeks may be required for the preliminary medical treatment before the optimum time for operation arrives. Moreover, much of the benefit of avertin is lost if the patient is disturbed during the stage of induction or during the hours immediately following the operation, when its prolonged sedative effect proves so valuable. It has been our custom to treat these patients in a medical ward until their operation, and then, for the next few days, in a single-bed side-ward, in quietness and subdued light.—We are, etc.,

L. CUNNINGHAM, M.A., M.B., M.R.C.P.

PHILIP HAWES, Ch.M., F.R.C.S.

Liverpool, June 18th.

Evipan Anaesthesia

SIR,—I was much interested in the article by Dr. Paul Kuhne (*Journal*, June 9th, p. 1029), in which he discussed the relative value of four different types of general anaesthetics administered to the same patient. On two occasions evipan sodium was used, the only difference being that in the second instance there was premedication with omnopon 2/3 grain and scopolamine 1/150 grain. On this occasion alarming symptoms were produced, and, according to Dr. Kuhne, the patient "at first sight appeared dead." In discussing this he expresses surprise:

"This is rather surprising, in view of the fact that some days previously evipan alone had given an excellent result. I can give no explanation of this, but the case illustrates clearly the depressant action of evipan on the respiratory centre and also its selectivity for that centre."

Might I suggest that the depressant effects which occurred have been due rather to the previous administration of a very large dose of omnopon combined with scopolamine, both of which are powerful respiratory depressants, rather than to evipan? Since Dr. Kuhne had previously given evipan without any ill effects, surely it is unscientific, to say the least, to ascribe the alarming symptoms which followed evipan plus premedication to the evipan and not to the premedication. The patient was the same; evipan was used on both occasions; the only new factor was that of omnopon and scopolamine. Yet Dr. Kuhne, after expressing his surprise and admitting his inability to give any explanation—(see quotation above), immediately afterwards claims that his very limited number of cases—namely, two—"clearly illustrates the depressant action of evipan on the respiratory centre and also its selectivity for that centre." By what logical process he has come to this conclusion I entirely fail to comprehend.

I would call his attention to the report on the clinical value of evipan from the Anaesthetics Committee of the Medical Research Council (*British Medical Journal*, July 8th, 1933, p. 63). This committee concluded that it is inadvisable to give any sedative before evipan sodium. Admittedly Dr. Jarman and Mr. Abel have used evipan preceded by omnopon and scopolamine, and have achieved excellent results (*Lancet*, July 1st, 1933, p. 18); yet they considered that such methods are contraindicated in feeble and toxic cases. Surely a patient who had been admitted with chronic otorrhoea of twenty years' duration, and who developed tenderness over the left mastoid and then had three anaesthetics within two months, might have been considered both toxic and enfeebled.—I am, etc.,

MONTAGUE SOLOMON, M.B., Ch.B., D.P.H.

Liverpool, June 9th.

Psychological Effect of Hysterectomy

SIR.—That the after-results described by Dr. Winifred Coppard are not invariably associated with hysterectomy is shown by the following case in my practice.

A woman, aged 32, having previously had three children, was suffering from severe menorrhagia. Three years ago my partner, Dr. G. R. Hughes, performed a subtotal hysterectomy, since when, of course, the periods have ceased. At first she felt unwell each month, but now she has no symptoms of any kind associated with the menstrual cycle. Whereas, however, before the operation her sexual appetite was normal, her husband now informs me that she has an insatiable sexual desire which makes very considerable demands on him for gratification. She has also become much more highly strung and nervous since the operation.

Of course, before the operation this nymphomania may have been suppressed owing to the fear of pregnancy; but, at any rate, in this case the frigidity described by Dr. Coppard did not ensue.—I am, etc.,

Barnet, June 21st.

S. VATCHER, M.D. Cantab.

The Cancer Problem

SIR.—The cachexia of malignant disease may hold a key to the understanding of part, at any rate, of the malignant process. That a true cachexia occurs apart from haemorrhage, infection of the growth, and mechanical interference with bodily function is generally agreed. It is not easy, perhaps, to be sure that the pure picture of malignant cachexia is strictly defined, but probably it will be accepted that anaemia, wasting, a thin, atrophic skin, and a tendency to secondary infections are constant features, while there is no evidence of failure of kidney function, or liver function, or of the circulatory system.

To approach the matter from another angle, and one, I think, which has something of the novel in it, the body tissues may be divided into three groups: one in which the cells continue to multiply actively after birth—for example, the epithelial and mucous surfaces, the blood-forming organs, the testes; one in which no new cells are formed after foetal life—for example, the brain and perhaps the kidneys; and one in which cellular multiplication occurs, but only in minor degree or after injury. This difference in cellular capacity has not, I think, been specifically studied in its relation to disease.

In malignant cachexia clinical observation and microscopical study point to the probability of the main injury being done to those tissues of the body which are still undergoing cell multiplication. Whether this injury consists in the abstraction from the circulation of some essential substance for cellular division or, which is improbable, the addition to it of some poison to such activity, may be revealed by study. If the cachectic state could be relieved life could be prolonged in fair health in symbiosis with the growth.

So far as active attack on the neoplasm is concerned, it seems established that apart from surgical removal most success attends efforts which regard the growth as a somewhat weakly rooted parasitic weed, and attack it with injurious agents which, while damaging the tissues of the host also, do not destroy their more established growth. X rays, bacterial toxins, metallic poisons, and prolonged pyrexia appear to be all occasionally successful, as I think might be expected if this simile from the garden is true, and it may well be that along the lines of such attack on the whole body will be found a means of medical cure of, at any rate, some varieties of malignant neoplasm.—I am, etc.,

Birmingham, June 17th.

HUGH DONOVAN.

Tuberculin

SIR.—Dr. Noel Bardswell is reported in the lay press to have stated at the annual meeting of the National Association for Prevention of Tuberculosis that in his experience distilled water had given the same results as tuberculin. That is not my experience. I have seen a rise of temperature of 4° F. after an injection of one millionth of a cubic centimetre of T.R. into a child of 8. Thinking this might be a nervous reaction, I injected 1 c.cm. of distilled water a week later. There was no reaction. I would be glad to know in what medical paper Dr. Bardswell's observations were first published.

I will gladly allow Dr. Bardswell to give me an injection of 1 c.cm. distilled water if he will allow me to give him 1 c.cm. bacillary emulsion. The results will be different. The distilled water will cause a slight haemolysis, and nothing more. The tuberculin will produce a lump. If a small exploring needle be stuck into that lump, per se suction applied from a Record syringe, some of the intracellular fluid will be drawn into the barrel of the needle. When this is expressed on to a glass slide it is found to consist of hundreds of polymorphonuclear leucocytes. That is a simple fact which anyone can verify. In the lump itself millions of leucocytes are eating and digesting particles of tuberculin. It is only fair to add that after an injection of 1 c.cm. bacillary emulsion anyone not immunized to this dose might find himself in a better world. Yet last week I gave a patient a final injection of 2 c.cm. bacillary emulsion. She had had *tabes mesenterica*, but after twelve months' tuberculin treatment the glands were no longer palpable, and she had gained a stone in weight. Does anyone seriously suggest that this could have been achieved by distilled water?

The comparative figures published by Gillespie of Belfast prove that tuberculin alone gives better results than sanatorium treatment without tuberculin. The deplorable neglect of tuberculin is due, I think, to two causes: men have not troubled to learn how to use it, and some who use it have not been over-communicative about the details of technique. I have been using tuberculin for over twenty years, and only during the past six months have I found a foolproof method of avoiding the severe reactions that sometimes follow large doses, and are due to superimposition. I now tell the patient not to come for another injection until the lump has entirely disappeared. This lump may persist for a week, a month, or even longer, but as long as it is present all the tuberculin has not been consumed. The patients feel at their best after the lump has gone.

If only those who are using tuberculin would unite to form a small society in which all knowledge would be pooled, the undoubted value of tuberculin would soon be recognized by the majority of doctors.—I am, etc.,

London, W.S. June 18th.

HALLIDAY SUTHERLAND.

Carcinoma of the Appendix

SIR.—Mr. Robert Rutherford's communication on carcinoma of the appendix (June 23rd, p. 1119) should, if it be necessary, once more drive home the importance of having a microscopical examination of every organ removed from the abdominal cavity. But it is surely supererogatory to suggest a course of deep x-ray therapy, for I thought it was established that if the peritoneal coat is intact the malignancy *qua* metastasis is nil.—I am, etc.,

London, W.1, June 24th.

R. CHRISTOPHER HOWARD.

Bile Salts for Empyema

SIR.—Mr. B. R. Sworn and Dr. T. V. Cooper, in their article on "The Treatment of Pneumococcal Empyema with Bile Salts" (June 23rd, p. 1117), express some apprehension as to the possible haemolytic effects which might follow absorption of sodium desoxycholate. They accordingly postpone treatment until the pus has become thick.

In the latter part of 1932, having convinced myself of the superiority of sodium desoxycholate over the taurocholate in the treatment of pneumococcal empyemata, I toyed with the idea of employing this salt in the treatment of pneumococcal pneumonia. To this end Dr. Macdonald of the Manchester University Physiology Department injected 10 c.cm. of a 10 per cent. solution (I quote from memory) of desoxycholate into the ear vein of a rabbit, with apparently no harmful consequences.

I mention this because it is my belief that, in the interests of quick healing, the walls of an empyema cavity should never be allowed to become thickened. If the thickness of the pus is an indication of the thickness of the pleura, then this can be avoided by the early employment of sodium desoxycholate. Furthermore, it would seem possible that the slight toxic manifestations which occasionally follow retention of the solution by the thin-walled cavity may be due more to the absorption of toxins from the lysed bacteria than to the antiseptic itself. For this reason I favoured thorough irrigation with a 10 per cent. solution followed by complete evacuation to the method of replacement.

May I, in conclusion, recommend this form of treatment as being worthy of further institutional study?—I am, etc.,

Alderley Edge, nr. Manchester, June 26th. H. R. DONALD.

District Almoners

SIR.—It is now generally recognized that almoners are indispensable in all our hospitals, and suggestions are being made that there should be district almoners, whose services would be available to all.

It is unnecessary to tell those who have worked on the visiting or resident staff of a hospital in recent years what an almoner can do, but there must be many in practice who have never been able to write upon a hospital patient's card, "Will the lady almoner please do this or that," and consequently many who do not realize how much an almoner can do to help to get the best results out of treatment. It will interest these to know that the almoner can usually do all those things for a patient that doctor or nurse cannot do; abdominal belts, and all other types of surgical appliances, extra nourishment or particular articles of diet, dressings, and special care of any sort can be obtained for those otherwise unable to obtain them.

Patients with cancer who need special care, with Graves's disease whose home conditions are unsuitable; children who have come from a distance for the specialist's opinion, who may be recommended treatment with rest in bed, and may not even have a bed to themselves—all these and many other similar cases can be dealt with by an almoner. Convalescence can be arranged, and although the patient at first mention of this may fear the loss of his job by so long an absence, yet it is usual to find that an almoner can approach his firm and get over this difficulty, often obtaining a grant partially to cover the cost.

Naturally the services of an almoner are not for the well-to-do, but with the assistance of a district almoner

practitioners could give better service to their patients, such a large proportion of whom are in varying degrees of domestic or financial difficulties. It would be interesting to hear the views of other practitioners on this subject, as it is felt that before further steps can be taken we ought to have an idea of the support that can be obtained.—I am, etc.,

London, S.W.1, June 18th.

GEOFFREY HALE.

Poisoning by Ground Ivy

SIR.—I am interested to note that Dr. W. G. Aitchison Robertson (June 2nd, p. 1008) states that the dermatitis produced by "ground ivy"—that is, *Hedera terrestris*—is similar to that caused by the American "poison oak or ivy" (*Rhus toxicodendron*). At one time I had a good deal of experience of the latter, and I think I am perhaps in the position of being able to suggest a form of treatment which, having been very satisfactory for *Rhus toxicodendron* poisoning, might be of value for the *Hedera* dermatitis.

In the former the rash, erythematous in type, spreads from the wrists to the eyelids and face, and may involve the whole body. The facial disfigurement is very marked, the eyelids being swollen and oedematous. Papules appear which develop into vesicles and even large bullae. Fever and constitutional disturbance are fairly marked in severe cases, but in spite of the alarming appearance of the patient I have never seen any case which gave me real anxiety. The causative agent is probably lobinol, and not toxicodendrol.

The treatment which I found most satisfactory was to paint the skin repeatedly with fluid extract of grindelia (U.S.P.). Copious drinks and suitable purgation, with a bland, non-stimulating diet, will, of course, be advisable in addition to the local treatment.—I am, etc.,

A. DANGERFIELD, M.B., F.R.C.S.Ed.

Corfe Castle, Dorset, June 19th.

Osteopathy

SIR.—My letter (June 2nd) in reply to Mr. Blundell Bankart's attack on osteopathy (May 19th) called forth several letters (June 9th and 16th) of the type one has learnt to expect on this subject. They do not call for any reply individually as they contained no considered criticism, and therefore were not useful except in so far as they give proof of the urgent necessity for the registration of qualified osteopaths.

I gathered from the letters that their authors had no knowledge of osteopathy, and therefore, perhaps, they are not aware that, although there are roughly a thousand persons practising as so-called osteopaths in the British Isles, of that number only about two hundred are qualified. When I speak of osteopathy, I mean the work of the qualified osteopath, not that of the chiropractor, the bone-setter, the naturopath, nor of any unqualified person.

We could all quote cases in which x-ray plates have not been correctly interpreted, and others in which prolonged and elaborate treatments have failed to cure, or even relieve, but these unfortunate happenings are not necessarily confined to osteopaths.—I am, etc.,

DOROTHY WOOD, M.R.C.S., L.R.C.P.

London, W.1, June 25th.

Obituary

MICHAEL GEORGE FOSTER, M.D., F.R.C.P.

We regret to record the death on June 16th of Dr. Michael G. Foster. Born on December 13th, 1864, in the house of his grandfather, Michael Foster, F.R.C.S., at Huntingdon, Michael George was the elder child and only son of Sir Michael Foster, K.C.B., M.D., F.R.S., afterwards the first professor of physiology at Cambridge, and for twenty-two years the secretary of the Royal Society, by his first wife, Georgina Edmonds. Educated at University College School, London, he entered Trinity College, Cambridge, in October, 1881, at an age recalling the custom of earlier centuries, and took his degree in 1884, at the same time as his friends W. Gordon of Exeter, G. P. Bidder of Cambridge, R. A. Bickersteth of Liverpool, J. G. Adami, Sir Arthur Shipley, and Sir Henry Head, with a third class in the Natural Sciences Tripos. Following his father's example, he went up to University College Hospital, qualified in 1888, became house-surgeon, and showed great promise in surgery. His future in this walk of the profession was as by a thunderbolt shattered by the onset of pulmonary tuberculosis, to which he had a strong hereditary tendency. But after two round voyages to Australia he began the hard life of a Continental physician, which he carried on for forty years, first at Maloja in Switzerland, then at Alassio, both for a short time, and later for many years at San Remo. Proceeding to the M.D. Cambridge in 1895, and elected F.R.C.P. in 1916, he subsequently practised at San Remo in the winter and at Harrogate in the summer. When war broke out he worked at the First Eastern General Hospital, Cambridge, and with Dr. John Foster Gaskell, the son of his father's pupil and colleague W. H. Gaskell, M.D., F.R.S., brought out in 1916 a well-written and finely illustrated monograph on cerebro-spinal fever, a subject on which he also wrote in the *Medical History of the Great War*. Later he was consulting physician to the troops in France and Flanders (with the rank of temporary colonel A.M.S.), was twice mentioned in dispatches, and received the O.B.E.

Michael Foster had a wide knowledge of health resorts, and as long ago as 1896 collaborated with the veteran authority Sir Hermann Weber in the article on "Climate in the Treatment of Disease" in Allbutt's *System of Medicine*; in 1933, after retirement from practice, necessitated by failing health, he brought out an admirable account of *Baths and Medicinal Waters in Britain and Europe*, inscribed "In affectionate memory of Sir Hermann Weber." After a week's struggle with pneumonia he finished his course on June 16th at the house at Fincham, Norfolk, where his mother (obit 1869) was born. He was buried on June 20th at Huntingdon.

We have received the following from Sir HUMPHRY ROLLESTON:

Many Cambridge men who fifty years ago were medical students will recall with regret the Michael G. Foster of Trinity, with the slim figure, healthy complexion, and high spirits of a boy. Entering the University when under the age of 17, he often spoke of this as an experiment in education, and in some respects no doubt it was a handicap. When he went up with a number of his friends—and he had a genius for friendship—to University College Hospital, he showed great promise in clinical work. But now came one of the many arrows of outrageous fortune that hit him; for, like his father, he developed signs of pulmonary tuberculosis, and the whole course of his life was thus altered. He practised for about forty years on the Italian Riviera, and became

an authority on the climatic treatment of disease. In spite of various family anxieties, the long illnesses and deaths of his two wives, and, in recent years, indifferent health, crippling rheumatism, and financial stringency from unsuccessful investments, he never lost his cheerful, kindly disposition, became embittered, or altered essentially from the pleasant companion his friends knew in the last century.

A deep sense of loss and very sincere regret has been felt in the Rotherham district by the passing, in London on June 12th, of WILLIAM STANLEY WILDMAN, at the early age of 48, after a severe illness borne with great fortitude. After passing through the Lancaster Grammar School and the London Hospital Dr. Wildman came to Rotherham in 1913, where he joined the late Dr. Percy Drabble in partnership, and remained a popular and esteemed figure in general practice till 1933, when a breakdown in health forced him to give up a large practice, and seek a quieter life; but he continued to practise in Tewkesbury for some months, till a further breakdown in health finally forced him to retire, and he died only a few weeks later. Dr. Wildman was honorary surgeon to the Rotherham Hospital for fourteen years, and took an active and enthusiastic part in the affairs of the local branch of the B.M.A., of which he was secretary for many years. He was a well-known and popular member of the Thrybergh Golf Club, and only a short year ago won the Fullerton trophy there. During twenty years of active practice in Rotherham he endeared himself to thousands by his tireless energy, patience, and skill, combined with a deep sympathy for all in suffering and trouble. He was much beloved, and widespread are the expressions of grief and deep sorrow at the news of his passing. J. J. H.

We regret to record the death, in a motor car accident on June 18th, of Dr. ARTHUR WILLIAM JAMES, who was well known for his pioneer work in developing the provision of ambulances for street accidents. Born in 1864, he was educated at St. Bartholomew's Hospital; he obtained the diplomas M.R.C.S., L.R.C.P. in 1887, and the D.P.H. of the Conjoint Board two years later. He graduated M.D. Brux. in 1897. His early medical appointments included those of clinical assistant to the Royal London Ophthalmic Hospital and resident medical officer to the Stoke Newington Dispensary and the Somerset and Bath Lunatic Asylum. Later he was medical officer in charge of the Duchess of Sutherland's Hospital for Naval Officers, and the California Hospital for Belgian Soldiers. He was a Fellow of the Royal Society of Medicine and a member of the Röntgen Society. Early in his London practice he had been impressed by the opportunities for saving life and minimizing injuries resulting from traffic accidents. His efforts brought into being the Metropolitan Street Ambulance Association, of which he was honorary secretary. In 1904 he contributed an article to these columns on the urgent need of ambulances for street casualties. Dr. James became a member of the British Medical Association in 1899, and is survived by his widow, who was with him when the fatal accident occurred.

News has been received from Alexandria of the death there, on June 14th, of Dr. ARTHUR ANDREW MORRISON, C.M.G., who had resided in Egypt since 1882. Born in Aberdeen in 1858, he received his medical education in that University, graduating M.B., C.M. in 1882, and proceeding M.D. four years later. He quickly attained distinction as a surgeon, and published articles in these columns on spinal analgesia and renal calculus. He was surgeon, and later consulting surgeon, to the Anglo-Swiss Hospital in Alexandria. Dr. Morrison was appointed British delegate to the International Quarantine Board of Egypt in 1897, and his public services in this and in other respects were recognized in 1925 by the conferment upon him of the C.M.G. He was a member of the Egyptian Division of the British Medical Association.

EPSOM COLLEGE

Lord Leverhulme presided over the eighty-first annual general meeting of the governors of Epsom College, which was held at the office, 49, Bedford Square, W.C., on June 22nd, and thanked the governors for having elected him president in succession to the late Lord Burnham. In presenting the council's annual report he stressed the importance of the appeal for new governors in order to enlarge the activities of the Foundation. He pointed out that possibly no profession felt the effects of a period of depression more acutely than the medical profession, whose voluntary work in such times was as much increased as their private practice was diminished. It was all the more necessary, therefore, to do all in one's power to help as many as possible of the large and ever-growing number of applicants for pensionerships and Foundation scholarships. This year the list of successful Foundationers contains the names of boys whose fathers practised in Glasgow, Stepney, Shropshire, Peterborough, London, Sierra Leone, the R.A.M.C., and the Royal Naval Medical Service.

The report was unanimously approved, and the proceedings ended with a warm vote of thanks to Lord Leverhulme for presiding at the meeting.

The following Foundationers were elected by the conjoint committee on June 13th: Daniel L. C. Thomas, William Farquhar Graham, John Urquhart Crichton, Colin C. R. Walker, Francis McLean Mathewson, Ian Young, and Donald M. Simmins. Denis M. W. Hartley was also elected as a special Foundationer. The following were elected pensioners: Mrs. Grace Elizabeth Hutchinson and Mrs. Alice M. A. Cockell.

Founder's Day at Epsom College will be celebrated on Saturday, July 28th—the second day of the cricket match between the school and an Old Boys XI. At noon there will be service in chapel; at 2.15 an assault-at-arms; at 3.30 Viscount Leverhulme, the president, will distribute the prizes, followed by tea on the cricket ground; and at 8 p.m. a performance of *H.M.S. Pinafore* will be given by the choral society.

The Services

INDIAN MEDICAL SERVICE: ANNUAL DINNER

The annual dinner of the Indian Medical Service took place in London at the Trocadero Restaurant on June 20th, with Major-General Sir Leonard Rogers, F.R.S., in the chair. The official guests were Mr. S. K. Brown, Military Department, India Office; Dr. N. G. Horner, *British Medical Journal*; Dr. E. C. Morland, *Lancet*, and Mr. F. H. Brown, *Times*; together with six officers on probation.

After the health of "The King-Emperor" had been honoured, the chairman, in proposing the toast of "The Service," declared that the I.M.S. still gave opportunities for good work, and that it would continue in the forefront. Recalling the primitive conditions under which hospital, laboratory, and administrative work had to be done when he joined the Service in 1893, he could point to many and great advances, both in equipment and in openings for research and clinical study. Whereas research used to be discouraged, now a man might give his whole time to it, with fine laboratories in the great centres of population and at hill-top institutes. For the progress that had been made during the past thirty or forty years Sir Leonard Rogers paid tribute to Sir Pardey Lukis, and to Sir Dawson Williams, a firm friend of the I.M.S. who made history by publishing in the *B.M.J.* a leading article headed "The Cinderella of the Services." On the military side there was now provision under the station hospital system, for better conditions of work; on the civil side the opportunities for lucrative employment had indeed gone, but with fewer posts there were fewer bad stations. The I.M.S. had friends at home in the Secretariat of State and high officials at Whitehall, and if it came the well out of the melting-pot this would be largely due to the support of the India Office. Recruitment of officers had been better in numbers and quality in recent months than at any time during the past twenty years.

The chairman's health was toasted with enthusiasm, on the proposal of Major-General Sir John Megaw, lately Director-General of the I.M.S., and now Sir Leonard Rogers's successor as president of the Medical Board, India Office. He said that Sir Leonard's achievements in medical research were known to the whole world, and every I.M.S. officer was proud of them; but even if he had not won that fame they would still regard him as the man who got things done. If their chairman's faith in the future of the I.M.S. were justified by the event this would be attributable in large measure to the efforts he himself had made to uphold its efficiency and prestige.

The chairman, after a brief acknowledgement of the unfailing kindness of his brother officers throughout his career, called upon Colonel J. Anderson for an interlude of stories. The final toast was the health of the honorary secretaries, Sir T. Carey Evans and Sir Richard Needham, to which the former replied, mentioning that there was a record attendance on this occasion, and that he had had many messages from officers in the Punjab and elsewhere.

The officers present at the dinner were:

Major-Generals: Sir John Megaw, H. R. Nutt, Sir Leonard Rogers, G. Tate.
Colonels: H. Ainsworth, J. Anderson, R. F. Baird, Sir S. R. Christophers, J. K. Close, J. Crimmin, P. Dee, A. B. Fry, J. Fuller-Good, T. A. Grainger, C. R. M. Green, W. H. Leonard, F. P. Mackie, A. J. Macnab, J. McPherson, Sir Richard Needham, J. J. Pratt, Ashton Street, R. G. Turner, W. S. Willmore, C. N. C. Wimberley.
Lieutenant-Colonels: W. G. P. Alpin, C. H. Barber, F. A. Barker, A. Buchanan, R. H. Candy, H. P. Cook, H. S. Cormack, D. Courts, D. G. Crawford, J. M. Dutton, S. C. Evans, J. K. S. C. D. Davies, C. Duer, H. R. Dutton, S. C. Evans, J. K. S. Fleming, C. A. Godson, G. F. Graham, V. B. Green-Armytage, A. F. Hamilton, J. B. Hanafin, H. Hingston, J. M. Holmes, E. V. Hugo, M. L. C. Irvine, S. P. Jaques, J. C. H. Leicester, I. M. Macrae, A. A. McNeill, E. C. G. Maddock, F. O. N. Mell, T. R. Mulrone, C. Newcomb, B. E. M. Newland, F. O'Kinealy, E. J. O'Meara, M. A. Rahman, H. Ross, W. S. J. Shaw, F. B. Shettle, G. M. C. Smith, W. C. Spackman, H. B. Steen, T. G. N. Stokes, H. Stott, J. Taylor, C. Thomson, E. O. Thurston, R. S. Townshead, A. G. Tressider, E. L. Ward, T. C. McCormie Young.
Majors: P. M. Antia, J. G. Bird, A. N. Bose, H. C. Brown, J. C. Chukerbuti, W. H. Crichton, J. A. Cruickshank, I. L. Donnelly, Sir T. Carey Evans, J. S. Galvin, N. H. Hume, G. R. McRobert, D. V. O'Malley, C. J. L. Patch, C. G. Seymour, E. A. C. Smith, H. Williamson, A. M. Fraser, R. T. Hicks, T. A. Chappell, L. A. Collins, F. H. Culshaw, F. J. Curtis, R. H. Dale, G. Bates, H. H. Bayley, D. A. S. Blair, C. H. T. Bond, J. G. Chappell, L. A. Collins, F. H. Culshaw, F. J. Curtis, R. H. Dale, T. M. Daniel, S. M. Davidson, W. H. Ekin, F. I. Evans, J. D. Ferguson, H. A. Hamilton, W. H. C. M. Hamilton, J. W. Hannay, E. E. Harris, G. R. Hawkes, N. G. Hulbert, R. M. Jones, A. M. Lester, F. D. M. Livingstone, E. B. McDowall, K. W. Martin, R. S. Morris, J. H. Moseley, W. S. Nutt, N. C. Oswald, J. R. Owen, A. R. Pope, M. S. M. Rayner, J. S. Ross, A. G. Salaman, S. K. Sen, D. A. Smith, L. W. Spratt, R. J. Still, F. B. Turner, R. W. D. Turner, P. A. Wallford, J. H. Walters, W. H. C. Watson, N. Whittaker.
Women: H. E. Dimsdale, W. F. Young.
Officers on Probation: Captain A. A. Pullar, Lieutenant R. D. de Solderhoff, Lieutenant R. L. H. Minchin, Lieutenant R. R. Prosser, Lieutenant T. K. White, Lieutenant E. Parry.

The King has conferred the Efficiency Decoration of the Territorial Army upon Major R. J. Bruce, R.A.M.C., T.A.

Universities and Colleges

UNIVERSITY OF OXFORD

At a congregation held on June 21st the degree of Doctor of Medicine (D.M.) was conferred on H. E. Harding.

UNIVERSITY OF CAMBRIDGE

At a congregation held on June 19th the degree of B.Chir. was conferred on S. J. Hadfield.

The following candidates have been approved at the examinations indicated:

THIRD M.B.—(Part I. Surgery, Midwifery, and Gynaecology):
A. G. V. Aldridge, T. G. Armstrong, K. C. Bailey, R. H. Bailey, A. G. V. Aldridge, T. G. Armstrong, K. C. Bailey, R. H. Bailey, G. Bates, H. H. Bayley, D. A. S. Blair, C. H. T. Bond, J. G. Chappell, L. A. Collins, F. H. Culshaw, F. J. Curtis, R. H. Dale, T. M. Daniel, S. M. Davidson, W. H. Ekin, F. I. Evans, J. D. Ferguson, H. A. Hamilton, W. H. C. M. Hamilton, J. W. Hannay, E. E. Harris, G. R. Hawkes, N. G. Hulbert, R. M. Jones, A. M. Lester, F. D. M. Livingstone, E. B. McDowall, K. W. Martin, R. S. Morris, J. H. Moseley, W. S. Nutt, N. C. Oswald, J. R. Owen, A. R. Pope, M. S. M. Rayner, J. S. Ross, A. G. Salaman, S. K. Sen, D. A. Smith, L. W. Spratt, R. J. Still, F. B. Turner, R. W. D. Turner, P. A. Wallford, J. H. Walters, W. H. C. Watson, N. Whittaker.
Women: H. E. Dimsdale, W. F. Young.
(Part II. Principles and Practice of Physic, Pathology, and Pharmacology): R. H. Bailey, A. M. Barrett, C. H. D. Bartley,

H. H. Bailey, R. L. Benison, A. T. Blair, T. B. L. Bryan, R. C. F. Cartwright, J. R. Chambers, A. C. E. Cole, J. Collinson, J. G. Connell, A. H. Dunkerley, J. F. Edwards, C. E. Elliott, W. A. Elliott, F. I. Evans, S. M. Evans, J. D. Fergusson, R. L. N. Graves, G. D. Hadley, E. A. M. Halsted, L. A. Hawkins, J. D. Hay, G. T. Hindley, N. G. Hulbert, A. Innes, B. S. Jones, A. M. Lester, R. E. K. Levick, M. W. Lloyd Owen, C. J. Martin, L. C. Martin, M. K. Martyn, H. B. May, W. G. Q. Mills, G. S. W. Organe, B. H. Page, C. G. Pantin, C. G. Parsons, J. P. S. Peck, G. T. Pitts, T. A. Ratcliffe, W. F. Richards, M. A. Rugg-Gunn, S. B. H. Saunders, T. L. H. Shore, M. S. Spink, R. J. Still, A. S. Tilt, R. W. D. Turner, J. H. Walters, G. L. Ward, M. Williams, H. W. Williamson, V. H. Wilson, R. M. Yeo. Women: C. M. Carell, R. A. Kelgren, D. J. Thompson.

UNIVERSITY OF LONDON

At a meeting of the Senate held on June 20th, Professor L. N. G. Filon, D.Sc., F.R.S., was re-elected Vice-Chancellor for the year 1934-5, and Dr. George Senter was appointed Deputy Vice-Chancellor for the same period.

Among the honorary degrees to be conferred on the occasion of the celebration of Foundation Day, 1934, are the D.Sc. upon Professor Karl Pearson, F.R.S., and the LL.D. upon Sir Cooper Perry, M.D.

Professorial Appointments

The following among other appointments were made to university chairs:

Anatomy (St. Thomas's Hospital Medical School), from September 1st, 1934: A. B. Appleton, M.A., M.D.

Bacteriology (Goldsmiths' Company's) (London Hospital Medical College), from October 1st, 1934: S. P. Bedson, M.D., M.Sc.

Medicine (British Post-Graduate Medical School), from October 1st, 1934, or as soon thereafter as may be practicable: F. R. Fraser, M.D., F.R.C.P.

Obstetrics and Gynaecology (British Post-Graduate Medical School), from October 1st, 1934: James Young, D.S.O., M.D., F.R.C.S.Ed., F.C.O.G.

Pathology (British Post-Graduate Medical School), from October 1st, 1934, or as soon thereafter as may be practicable: E. H. Kettle, M.D., F.R.C.P.

The title of Emeritus Professor of Bacteriology in the University was conferred on William Bulloch, LL.D., M.D., F.R.S., on his retirement from the Goldsmiths' Company's chair of bacteriology at the London Hospital Medical College; and that of Emeritus Professor of Ethnology in the University on C. G. Seligman, M.D., F.R.C.P., F.R.S., on his retirement from the University chair of ethnology at the London School of Economics.

Heath Clark Lectureship

The date of the appointment of Professor Karl Pearson as Heath Clark Lecturer was changed from 1934 to 1935, and Dr. L. W. Hackett, assistant director of the International Health Division of the Rockefeller Foundation, was appointed for the year 1934.

UNIVERSITY OF LEEDS

At a meeting of the University Council on June 21st, Mr. E. R. Flint, F.R.C.S., was elected to the chair of clinical surgery. He will also retain the directorship of surgical research.

UNIVERSITY OF GLASGOW

At a ceremony on June 21st, presided over by the new Chancellor of the University, Sir Daniel Stevenson, the honorary degree of LL.D. was conferred upon Dr. René Leriche, professor of clinical surgery in the University of Strasbourg.

The following higher degrees were conferred on the same day:

M.D.—(1) With honours: D. Baird, J. M. Johnston. (2) With commendation: Margaret E. R. London. (3) Ordinary degree: W. Bain, W. Elyth, J. B. L. McKendrick, Elizabeth M. Pollock. D.Sc.—W. J. Hamilton, M.B. Bell, T. Nicol, M.B. Ch.M.—A. M. Clark (with high commendation).

The Board of Curators has appointed Dr. Archibald Wilson Harrington to the Muirhead chair of medicine, in succession to Professor Walter K. Hunter, who will retire on September 30th.

The Senate announces that the History of Medicine Prize has been awarded to Dr. William J. Rutherford.

Medical Notes in Parliament

[FROM OUR PARLIAMENTARY CORRESPONDENT]

This week the Commons put the Debt Clearing Houses and Import Restrictions Reprisals Bill through all stages, and completed consideration of the Milk Bill. The Betting and Lotteries Bill was down for second reading.

The House of Commons has read the Finance Bill a third time. Mr. Chamberlain told the House he was confident the reliefs given in the Bill would not need to be withdrawn in future, and would, he hoped, be followed by other concessions.

In the Commons, on June 25th, the South Devon and East Cornwall Hospital, Plymouth, Royal Albert Hospital, Devonport, and Central Hospital, Plymouth (Amalgamation, etc.) Bill was considered on report, and ordered for third reading.

Consideration of the Shops Bill by a Standing Committee of the House of Commons was completed on June 26th.

The Lords, on June 20th, passed the South Middlesex and Richmond Joint Hospital District Bill, which was thereafter read a first time in the Commons.

In the House of Lords, on June 22nd, the Royal Assent was given to the Workmen's Compensation (Coal Mines) Act, the Statutory Salaries (Restoration) Act; the Protection of Animals (Cruelty to Dogs) (Scotland) Act, the Licensing (Permitted Hours) Act, and the Birmingham United Hospitals Act.

In the House of Lords, on June 26th, the Marriages Provisional Orders Bill, and the Adoption of Children (Workmen's Compensation) Bill were read a second time. The Road Traffic (Compensation for Accidents) Bill was read the third time and passed.

Price of Milk to Schools

The House of Commons, on June 19th, again went into committee on the Milk Bill.

On Clause 11, which deals with contributions from the Exchequer towards expenses of milk marketing boards, Sir F. Acland moved an amendment to ensure that not less than half of the money provided by Parliament should be expended in repayment to the Milk Marketing Board in respect of milk for consumption by children attending public elementary schools, or by mothers, or by children below school age attending clinics under schemes approved by the local public health authority. He said that the Bill contained nothing to provide that any money should be spent for this purpose at all. From the point of view of the farmers, quite as much as from that of the children, it would pay over and over again to give as large a proportion of this money as possible for milk for consumption by the school children and other persons covered by his amendment. Dr. Elliot said that the proportions they would spend would be about six-sevenths for school milk and one-seventh for publicity. The proposals with regard to publicity had been gone into, on behalf of the Milk Marketing Board, by one of the greatest experts in the country, and the sum which was at present suggested as reasonable to devote to that object was a sum of, say, £50,000 a year in England, or £100,000 in all, which left the English share of the grant £430,000 a year, or £860,000 in all.

The amendment was withdrawn.

On the motion that the clause should stand part of the Bill, Dr. Elliot, in reply to Sir Stafford Cripps, said that it was intended to work on the schemes which had been in operation for some time under the National Milk Publicity Council. Those schemes, which were now supplying something like 900,000 children with milk, were working well. Milk was at present supplied at one penny for one-third of a pint, and it was hoped, as soon as they got sanction to proceed under the Bill, to reduce it to one halfpenny. They hoped that halving the price would act as an excellent advertisement. The extent to which they could spread the milk at

one halfpenny depended on the arrangements which they were able to make with the Board and the arrangements which the Board could make with the distributors. If the Bill became law in good time, they would be able to bring the scheme into operation the moment the children returned from their school holidays. He hoped, within the next two years, that a scheme could be worked out which the Board might itself be able to continue after the expiry of State assistance.

On Clause 12—extension of functions of milk marketing boards—Dr. Elliot moved to insert words providing that the milk had been produced in circumstances determined by the Minister or by the Board with the object of securing, so far as practicable, that it was pure and free from the infection of any disease. This would enable the proposals to be continued by agreement and not necessarily by an order. The amendment was agreed to. Dr. Elliot moved a further amendment to clear up a doubt which had been expressed as to whether the provisions of the Agricultural Marketing Act, 1931, would enable the Milk Marketing Board to fix the price of milk to be sold to schools at a lower price than the price of liquid milk sold to other consumers. He said the whole House desired to allow this discrimination in price. The amendment was agreed to and the clause as amended was accepted.

On Clause 13—interpretation—Sir ARNOLD WILSON moved to insert a definition of pure milk. He said his amendment would exclude pasteurized milk and milk treated by heat in other ways from the financial benefit of Clause 9. The Hopkins report gave grudging support to pasteurization; it admitted that vitamin C was destroyed to a greater or less degree by the process of pasteurization, and said that the resulting deficiency could be corrected by the use of orange or lemon juice, which was now easily obtainable. Sir Arnold denied that this juice was easily obtainable. It cost from sixpence to one shilling weekly per child, and in many parts of England was practically unobtainable. The Hopkins report mentioned that in America a large number of children who were fed on pasteurized milk became rickety, and the deficiency was only cured by an antiscorbutic diet of lime-juice. The Chairman intervened to say there was no reference to pure milk anywhere in the Bill, and as the expression did not occur it would not be in order to propose a definition of pure milk. Sir Arnold Wilson said the words "pure and free from the infection of any disease" occurred in the definition which had just been moved by Dr. Elliot. The Chairman insisted on his ruling, but said the matter raised by Sir Arnold Wilson might subsequently be brought up as an amendment on Clause 9. Clause 13 was then approved, and the committee stage ended.

On June 25th the Milk Bill was further considered on report in the House of Commons. On Clause 9 (payments for securing pure milk supply), Sir STAFFORD CRIPPS moved an amendment to provide that in cases of default by local authorities in England or Scotland the Minister of Agriculture or the Secretary of State for Scotland should exercise all the powers of inspection of dairy cattle at present conferred on the local authorities. Mr. SKELTON said that once they linked up the system of accredited herds with encouragement in the production of pure milk they would get a stimulus to the extension of the system of clinical inspection of herds which would do a great deal more than could be done under the Diseases of Animals Act. The amendment was negatived.

Sir ARNOLD WILSON moved an amendment to define milk "pure and free from the infection of any disease." The amendment proposed to exclude from the scope of the Bill pasteurized milk or milk heated in other ways. It also proposed to set up a scientific technical body on which the Ministries of Health and Agriculture would be represented, which would advise from time to time on what might reasonably be regarded as pure milk, free from the infection of any disease. Sir F. FREMANTLE said he could not understand how anyone could suggest that they were going to get a standard of bacteriological purity and nutritional content by a public inquiry. All they could do was to see that the standard was revised from time to time, and, if it was thought advisable, to inform Parliament as to the grounds on which the standard was laid down. He did not think the amendment was required. Mr. SKELTON said the amendment would not quite succeed in doing what its supporters wished. The main method which it was intended to apply to secure a

supply of pure milk free from infection was the initiation of a scheme for the cleansing of the herds, and he thought the House would agree that that was the right method. If the amendment were accepted it would go far to prohibit the pasteurization of milk. There was no intention that any development of pasteurization should take the place of the cleaning up of the herds as far as this clause was concerned. It might well be, however, that under the Bill it would be worth while to make some investigation into the proper method of pasteurization. To make the granting of money for the purpose of cleaning up the herds dependent on the milk reaching a particular standard of bacteriological purity and nutritional content took them very far from the vitally important purpose of the clause.

The amendment was withdrawn, and the report stage was concluded.

Health of the Country

Departmental Estimates

In the House of Commons, on June 20th, Sir HILTON YOUNG made his annual statement on the estimates of the Ministry of Health. He said there was an increase of £18,500 over the estimates of the previous year, as the result of additional work on slum clearance and rural water supplies. Between 1919 and 1934 the vote for the Ministry of Health had increased from £13,000,000 to £71,000,000. Of this latter sum £40,000,000 was the block grant to the local authorities, £11,500,000 the State expenditure on pensions, and £14,000,000 the State expenditure on housing. He desired to take advantage of the debate to give an account of the work of the Ministry during the year in relation to national health, and in particular of the standard of national physique and health as shown by the incidence of, and the resistance of the population to, disease. The general death rate of the nation showed a downward tendency; compared with five years before, the standardized death rate for 1932 was 10 per cent. lower after taking account of the fact that owing to the falling birth rate the population was annually getting older in its average age. During the last ten years 40,000 more infants under 12 months had been saved each year than were saved at the beginning of the century. The improvement was due basically to the education of the mothers of the country in the care of infants. He offered a tribute to the work done by the 1,340 ante-natal clinics in the country and the 2,820 infant welfare centres. In the thousands of health visitors and nurses from these centres they had an army for health from whose work they derived great advantage. In the last fifteen years the death rate of children under 5, from bronchitis, diarrhoea, and measles, has been cut by more than half. The death rate figures in respect of adults also showed the results of faithful work by the medical profession and the hospitals, and by the administrators of the public health services. Brilliant successes had been secured against disease conveyed by outside carriers like water or milk, or by some "bug" or insect, or by food. Difficulties arose when infection was carried from person to person. The line to work on to prevent such an infection was to see that overcrowding was avoided. When the Ministry said that overcrowding clamoured for a national remedy it did so not only for social reasons but to prevent disease. The health work of the country had won a brilliant victory against what seemed the most intractable of diseases—namely, tuberculosis. In the ten years up to 1933 the death rate from tuberculosis had decreased by 22 per cent. This was due, in the first place, to the knowledge that isolation was the principal preventive of the disease. It was due also to the general improvement of social conditions, and in particular to the improvement in child welfare and child care. However far the campaign against tuberculosis was carried they would never get rid of that disease until they were rid of the slums. The statistics of lunacy and mental deficiency gave a less favourable impression, but were deceptive. The increased average age of the population probably accounted for the increase in lunacy, which was a disease of advanced years. The apparent enormous increase in mental deficiency was due to better ascertainment. They were for the first time undertaking a great service for the segregation of mental deficients. A report had been published during the year on the difficult problem of the sterilization of the mentally unfit. As an individual he was impressed by the strength of the reasons

given by the committee in support of its recommendations. He was equally impressed by the unanimity, and, as an individual, he could not see the least difficulty in approving the recommendations. But Ministers must remember that this was a novel question and had not been thought out by the nation. Great organizations such as the Churches should have adequate time for thinking out this matter. It would be wrong for Ministers to suggest any national policy until they were quite sure they were making no proposal which did not offend against the national conscience. The maternity death rate, the Minister continued, had not decreased like other death rates during the last twenty years. By intensive study they knew the reason for this—namely, that there were bad local patches in maternity welfare work. He asked the responsible authorities in localities where the rate was above normal to realize the service that could be done to public health by following up inquiries into the cause of the local variation. The remedy was to ensure that the maternity service was as good in every locality as it was now in the best. The Ministry of Health pursued that policy, and could report that the country now had 147 more ante-natal clinics than a year ago, and that more births took place under the supervision of such clinics. There was also an increase in the number of maternity beds. Speaking generally of the health services of the country, the Minister said the work had been much assisted, and knowledge had been enormously increased, by the systematic review of the Ministry of Health. Since the Act of 1929 made that review possible the Ministry had already dealt with the health services of the counties, the county boroughs, and the metropolitan boroughs, and it was going on to deal with the smaller authorities. Two things were sought in these reviews besides a general increase in efficiency. First, it wished to press forward the movement inaugurated by the Act of 1929 for taking the treatment of disease out of the Poor Law, particularly by the transfer of institutions dealing with ill-health to the public health committees. In London sixty institutions had been taken out of the Poor Law. Mental cases, health cases, old persons, etc., were now treated in specialist institutions; this meant an increase in efficiency and also an increase in the area covered by such institutions. After a survey of the water supply of the country as affecting the public health, and of the measures which had been taken to relieve the shortage consequent on the long drought, Sir Hilton Young referred to the Government's housing activities, particularly its slum clearance campaign. In 1933-4, he said, they had secured the declaration of 2,250 slum areas, covering 37,000 houses and 172,000 people, apart from individual houses. The rate of progress was increasing monthly, and if the acceleration were maintained the White Paper programme would be achieved in five years. The present rate of demolition was not good enough to carry out the programme, and must be speeded up. During the year he had reorganized the housing work of the Ministry, and had put together town planning and housing into a single department, under an officer with the special status of Director of Housing. There was a town planning advisory council, so that expert persons could aid the Ministry. The staff of the Ministry had been increased to cope with this additional work. The year had seen a boom in the building of small houses in London. In the half-year ended March 31st, 1934, 44,000 more houses were built than in the preceding half-year, and 34,000 more houses were built by private enterprise. The country was now building at the rate of 300,000 houses a year, and at the rate of 155,000 a year for lower-paid wage-earners. That astonishing activity followed the Act of 1933, which altered the system from a general subsidy into a controlled subsidy for slum clearance. The production of houses was rapidly overtaking the shortage, but the reduction in prices would not be seen until the shortage was actually overtaken.

Opposition Criticism

Mr. ARTHUR GREENWOOD said he shared the Minister's sorrow that no impression had yet been made on the maternity death rate. If Sir Hilton could produce any scheme to reduce that rate he would have warm support from the Opposition. He criticized the Minister's past policy in respect of water shortage, and particularly the "massacring" of rural water schemes which the Labour Government had left behind in 1931. He also questioned the Minister's statement about

housing, and said that under the Housing (Financial Provisions) Act of 1933, which was to produce houses to be let at reasonable rents aided by guarantees from building societies, guarantees had been given up to the end of March this year in respect only of 1,631 houses. In addition, guarantees in respect of 8,400 houses had been promised or were in active negotiation. Private enterprise last year built more houses than it did the year before, but these did not compensate for the local authority's houses which had not been built owing to the change of policy.

Mr. GEORGE GRIFFITHS said the total number of deaths from tuberculosis in 1932 was 32,000. Dr. Bradbury, who had been closely investigating the disease in Jarrow and Blaydon for over two years, put the cause of tuberculosis under three headings: (1) the bad sanitary condition of houses; (2) overcrowding, which Mr. Griffiths contended the Ministry of Health promoted by sending auditors who drew attention to arrears of rent on municipal houses and forced housing committees to allow tenants to take a second family into the house; and (3) poverty, which Dr. Bradbury stated was the chief cause. Mr. Griffiths said, as chairman of the Tuberculosis Subcommittee of the West Riding County Council, that scores of miners' wives in that county got tuberculosis as the result of under-feeding. The medical officer of health for the West Riding stated that the health of the children in schools revealed surprisingly little evidence of malnutrition, but this result was obtained by the self-sacrificing bravery of the mothers. Sir George Newman had stated that at least half of the mothers who died in childbirth could be saved if they were properly looked after. The reason they died was that they had not the necessary strength. When wages went down in this country diabetes went up. There were in this country 196,000 diabetic people. As the 1932 Health Insurance Act said a man must forfeit medical benefit when out of work for two years and nine months, he calculated that out of 100,000 unemployed who had forfeited medical benefit there must be at least 400 diabetics who were deprived, through that Act, of the means of getting insulin. The Government had also taxed, at a rate of 25 per cent., the imported needles which the diabetics had to use. The latest price for a bottle containing 100 units of insulin was 1s. 10d., and some people had to take 500 units a week. He asked the Minister to promise that the diabetic who had been deprived of other medical benefits should continue to get insulin.

Grant for the Post-Graduate School

Captain ELLISTON mentioned the subject of health education, and asked the intentions of the Government towards the British Post-Graduate Hospital and Medical School. The £250,000 voted for these before 1931 had been reduced to £100,000, but leaders of British medicine hoped the Government would now take a more liberal view. These leaders wished to see in London a post-graduate medical school which would be a rallying point to medical men from all parts of the Empire and of the United States, who now went by hundreds to work in Paris, Vienna, Berlin, and Rome. Yet London had material to rival any capital in Europe, and the teaching could be supremely well given. Little could be done to improve the efficiency of the health departments of the country. It remained to teach the public to make use of the facilities provided by those departments. All the organization of health visitors, doctors, and laboratories, and all the expenditure on maternity and infant welfare, on nutrition, and on countering tuberculosis and venereal disease was wasted unless the public could be taught to use the facilities provided. The Minister had encouraged the Central Council for Health Education in its work, but that Council had no funds, and it was to be regretted that the Minister had applied in vain recently to the Association of Municipal Corporations and the County Councils Association to get their constituent bodies to support the Central Council. He asked the Minister to advise local authorities that a small expenditure to support the Council would mean a great saving in the cost of public health departments and in preserving the health of the people. It was also to be regretted that the magnificent unit for the production of moving pictures which had belonged to the Empire Marketing Board had not been retained for the purposes of the Ministry of Health. Some matters of great concern to the public—for instance, nutrition—were not dealt with by existing organizations. He asked the Minister, when

that cinema organization had finished its work for the Post Office, to consider whether it could produce for the Ministry of Health a series of films which would have great educational effect. He appealed to the Minister with regard to the local government officers, who were doing magnificent work. It was a hardship that superannuation was only in force in some areas.

The debate was adjourned. It is expected that medical members will have an opportunity, on its resumption, to discuss the sections of the Minister's speech dealing with public health.

Administration of the Tuberculosis Order.—On June 18th Dr. ELLIOT informed Mr. T. Williams that there were no qualified veterinary surgeons employed by the Ministry of Agriculture exclusively on duties under the Tuberculosis Order, 1925. That Order, in the main, was administered by

local authorities and their veterinary staffs. Imported cattle were examined in the landing place by the Ministry's veterinary staff for tuberculosis as well as for other scheduled contagious diseases. On this work eleven veterinary inspectors were employed full time.

East African Climate and Europeans.—Mr. LEWIS, on June 19th, asked Sir Philip Cunliffe-Lister if his attention had been called to a suggestion put forward by the Kenya Society for Race Improvement, supported by a number of "doctors in practice in Nairobi," that research should be undertaken into the effects of the East African climate on European residents. He also asked whether, in view of the bearing of this question on the problem of white settlement, the Minister would initiate some such inquiry. Sir PHILIP CUNLIFFE-LISTER replied that he knew nothing of this suggestion beyond what had appeared in the Press. Mr. Lewis would not expect him to form an opinion on such material.

Medical News

The Section of Obstetrics and Gynaecology of the Royal Society of Medicine has issued invitations to all members of the Medico-Legal Society to a meeting at 1, Wimpole Street, W., on Friday, July 6th, at 8.15 p.m., when there will be a discussion on "The Nature of Sex and its Sociological and Legal Implications." Members of the Medico-Legal Society are invited to take part.

The ninety-third annual meeting of the Royal Medico-Psychological Association will be held at the Guildhall, Northampton, on July 4th, 5th, and 6th, under the presidency of Dr. Daniel F. Rambaut. The annual dinner will be held in the Guildhall on Wednesday, July 4th, at 8 p.m.

As already announced, the Queen will open the new Students' Hostel at the London Hospital Medical College on Tuesday, July 3rd, at 3.30 p.m. The prize distribution will be on Tuesday, July 10th, at 3 p.m., by the Right Hon. Walter Elliot, LL.D., M.B., Minister of Agriculture and Fisheries.

Lord Derby will open the Medical Section, which has been established at British Industries House, Marble Arch, on Thursday, July 19th, at 3 p.m. This section comprises a comprehensive display of British-made hospital medical and surgical requirements, and also a twelve-bed ward, two operating theatres, and a number of accessory rooms. The theatre and ward block unit occupies over 12,000 square feet on the ground floor of the building, and is constructed from the plans of Messrs. Adams, Holden, and Pearson, who also are the architects for the new Westminster Hospital. The work is being carried out under the supervision of the Advisory Council of the Medical Section, of which the chairman is Dr. Alfred Cox. All members of the medical profession and others interested in hospital administration are invited to the opening ceremony and to use the Section afterwards. It will be open daily from 10 a.m. to 5 p.m.; Saturdays 10 a.m. to 1 p.m. Admission on presentation of professional card.

On Friday, July 6th, at 8.45 p.m., Dr. A. Salusbury MacNalty of the Ministry of Health will take the chair at the Princess Elizabeth of York-Children's Hospital, Shadwell, E., for an address on "Charles Lamb" by Mr. R. Ellis Roberts, literary editor of *Time and Tide*. Visitors are welcomed.

A post-graduate course on diseases of the urinary tract will be held at the Hôpital Cochin, Paris, from July 2nd to 21st, under the direction of Professor Chevasu. Further information can be obtained from the Faculty of Medicine.

The Fellowship of Medicine's programme includes a lecture-demonstration on high blood pressure, at 11, Chandos Street, W., on July 10th, at 2.30 p.m.; a week-end course in general medicine and surgery at the General Hospital, Southend-on-Sea, on July 7th and 8th; a fortnight's course in dermatology at Blackfriars Skin Hospital from July 9th to 21st; a three weeks' course in urology at All Saints' Hospital from July 9th to 28th.

X-ray demonstrations for M.R.C.P. candidates will be given at 11, Chandos Street, on July 2nd, 4th, and 6th, at 8.30 p.m., and a demonstration of dermatological cases at the National Temperance Hospital, Hampstead Road, N.W., on July 14th, at 3 p.m.

A Leverhulme Research Fellowship has been awarded to E. Ashley Cooper, D.Sc., lecturer in chemistry, University of Birmingham, the subject of his investigation being the activity of enzymes of bacteria.

The issue of the *Urologic and Cutaneous Review* for June is devoted to prostatic resection.

The issue of the *Schweizerische medizinische Wochenschrift* for June 9th is a Festschrift in honour of the centenary of the foundation of Bern University, and contains portraits of the most distinguished professors of the medical faculty during the last hundred years.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, W.C.1.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated. Correspondents who wish notice to be taken of their communications should authenticate them with their names, not necessarily for publication.

Authors desiring REPRINTS of their articles published in the *British Medical Journal* must communicate with the Financial Secretary and Business Manager, British Medical Association House, Tavistock Square, W.C.1, on receipt of proofs. Authors overseas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

All communications with reference to ADVERTISEMENTS, as well as orders for copies of the *Journal*, should be addressed to the Financial Secretary and Business Manager.

The TELEPHONE NUMBER of the British Medical Association and the *British Medical Journal* is EGSTON 2111 (internal exchange, four lines).

The TELEGRAPHIC ADDRESSES are:

EDITOR OF THE BRITISH MEDICAL JOURNAL, Aitiology Westcent, London.

FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate Westcent, London.

MEDICAL SECRETARY, Mediscera Westcent, London.

The address of the Irish Office of the British Medical Association is 18, Kildare Street, Dublin (telegrams: *Bacillus, Dublin*; telephone: 62330 Dublin), and of the Scottish Office, 7, Drumshburgh Gardens, Edinburgh (telegrams: *Associate, Edinburgh*; telephone: 24361 Edinburgh).

QUERIES AND ANSWERS

Results of Operations for Elephantiasis

"I. S. Q." would be glad of any information from surgical readers as to the end-results of either the Koonoleon or Sistrunk procedures for elephantoid conditions of the lower extremities.

Exercises for Lumbago

"W. T. H." writes: Can any reader give me information regarding curative or remedial exercises for lumbago? I seem to remember some discussion in the *Journal* about two years ago, concerning such exercises or manipulative movements. Is there any book dealing with the subject?

Pruritus with Jaundice

Dr. ALEX. P. GREEN (London, S.E.) writes: In answer to "P. J. M." (June 16th, p. 1103), I remember some years ago giving an injection of pilocarpine nitrate for just such a condition as he mentions, with very good results.

Orchitis After Prostatectomy

Dr. A. J. C. TINGEY (Hastings) writes, in reply to the inquiry by "X. Y. Z." (June 9th, p. 1061): Orchitis is a common sequel to *Bacillus coli* infection of the urinary tract. I suggest that a specimen of the patient's urine should be examined by a bacteriologist, and, if positive, the infection should be treated. Among the urinary disinfectants in general use pyridium, neotropin, and caprokol are convenient to prescribe, and are well tolerated.

*Income Tax**Motor Car Allowance*

"P. N. G." inquires what he should claim in respect of a car he has "recently" purchased.

* So far as out-of-pocket expenses for running costs—including licence, insurance, etc.—are concerned they should be treated as ordinary professional expenses, though the local inspector will probably insist on some set-off from the total expenditure for private use of the car. As the car has been purchased recently the deduction of those expenses will, presumably, not affect his current year's liability. In addition, he can claim the "depreciation" allowance, and as that is deducted from the profits as an allowance for the year of assessment, there is no reason why a claim for an allowance of 20 per cent. of the cost price should not be made as for the current year—or, at any rate, for the appropriate number of months between the date of purchase and April 5th, 1935.

Employment of Assistant

"A. M." has "engaged an assistant, at £400 per annum, living out." The assistant has a car of a more expensive make and involving a larger consumption of petrol and oil than "A. M." would have supplied. The yearly mileage is about 3,500. What arrangement is considered reasonable?

* This is, of course, one of the minor matters which it would have been well to have settled beforehand. As it is, the general basis of a suitable arrangement would seem to be that "A. M." should pay as a car allowance to his assistant what would have been the probable cost (including depreciation, repairs, etc.) of providing an adequate car for his use. Possibly some addition should be made on the ground that with a better car the assistant can take a larger share of the work, or cover his share more effectively. For income tax purposes "A. M." will, of course, deduct the amount he pays.

LETTERS, NOTES, ETC.

Ethyl Chloride Analgesia in Minor Surgery

Dr. JOHN FREDERICK BRISCOE (London, S.W.) writes: The contribution by Dr. A. Amoils under the above heading in your issue of June 23rd (p. 1143) I can thoroughly endorse. In the hands of the skilled and busy practitioner this method is simple and practical. But as regards dental extraction the operator *must* be an adept with his forceps. I had the opportunity of the friendship of Dr. Peake at the Durban Hospital, South Africa, two years ago, and I took him three Lascars with bad teeth and innumerable stumps in a pyorrhoeal mouth. Under the minute he removed fifteen stumps from one Indian subject without any upset whatsoever. Dr. Peake's practice is as follows: "He has a piece of lint 8 in. by 5½ in., with two drachms of the ethyl chloride sprinkled upon it. The patient is on an upright couch; the prepared lint is held a few inches before the face, and he is told to keep blowing into it. No gag is used. After about two minutes the stumps are skillfully and rapidly extracted. The head is turned aside over a small basin, and the mouth syringed out with pale Condy." Not least important, all instruments and hospital furniture are absent within a quiet room.

* We take this opportunity to correct a typographical error in Dr. Amoils' letter. In the description of the method of administration, "(eight-inch)" should read "(eighth-inch)."

Imported Insulin

Mr. J. WICLIFFE PECK, Ph.C., F.C.S., chairman of the firm of C. L. Blencard (1934) Ltd., importers of Danish insulin, writes: In your issue of June 9th, under "Medical Notes in Parliament," you give a report of the interview which the Chancellor of the Exchequer granted to a deputation from the Parliamentary Medical Committee, on the removal of the tax on imported insulin, and a further report of the debate which ensued in the House of Commons on the repeal of the Customs duty thereon. Certain statements which, according to your reports, were made on these two occasions are without foundation, and therefore I trust you will give equal publicity to the following comments. A member of the deputation is reported to have stated: (1) "The Danes had buildings and equipments free. Raw pancreas and labour were both cheaper." Danish raw pancreas is not so cheap as imported frozen pancreas from the Argentine or pancreas from English slaughterhouses. The other statements quoted are devoid of foundation. (2) "And their product exempted from income tax." This is a totally misleading statement. (3) "It was evident that the Danes were prepared to under-sell British manufacturers however much these reduced the price, and would so secure the British market." This assumption is both without foundation and absurd. In the House of Commons speakers are reported to have said: (1) "The committee should be asked to pass a clause which would probably have the effect of handing over to a foreign monopoly the manufacture of insulin." There is no foreign monopoly in existence, nor can I see the slightest prospect of one arising. (2) "Denmark was able to produce insulin more cheaply than we were, partly because of the subsidized nature of the manufacture, partly because of the ease with which the Danes could obtain the pancreas, and partly because of the cheapness of the pancreas." These suggestions are fictitious. (3) "This country produced finer and purer insulin than any other country in the world." It would be interesting to learn on what grounds the speaker makes this claim. I regard it as without foundation.

Medical Reunion in Vienna

With reference to the notice in this column on June 16th (p. 1104), the committee has decided to postpone the reunion of doctors in Vienna to July 29th, in accordance with general request. The meeting will therefore be held from July 29th until August 4th, instead of July 9th to 15th, as originally intended.

By Air to Bournemouth

For the benefit of members of the British Medical Association who may wish to travel by air to the Annual Meeting at Bournemouth next month, Provincial Airways, Ltd., of Croydon are prepared to reduce their fares from £2 10s. to 35s. single. To enable members to reach Bournemouth in time to attend the morning session of the Scientific Sections, a machine will leave London at about 8.30 a.m. Those who are interested should communicate direct with Provincial Airways, Ltd.

Corrigendum

In our review of *Individual Psychology and Practice*, published on June 23rd (p. 1122), the name of Dr. C. M. Bevan-Brown, one of the four contributors to this pamphlet, was incorrectly given.

As announced in our advertisement pages last week, a new company, Ciba Limited, 40, Southwark Street, London, S.E.1, is taking over the pharmaceutical department of the Clayton Aniline Company Limited, as sole concessionaires for the Ciba Brand pharmaceutical products. The formation of the new company coincides with the jubilee of the Ciba firm in Basle.

Watson and Sons (Electro-Medical) Ltd. (Sunic House, 43-47, Parker Street, W.C.2) have issued a new leaflet dealing with infra-red and radiant heat equipment, and including some new types of apparatus; also a price list of their medical arc carbons. Copies may be had gratis on application.

Vacancies

Notifications of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 35, 36, 37, 38, 39, 40, 41, and 44 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 42 and 43.

A short summary of vacant posts notified in the advertisement columns appears in the *Supplement* at page 344.

THE JOURNAL OF THE BRITISH MEDICAL ASSOCIATION

EPITOME

OF

Current Medical Literature

JANUARY TO JUNE, 1934

London:

PRINTED AND PUBLISHED AT THE OFFICE OF THE BRITISH MEDICAL ASSOCIATION,
TAVISTOCK SQUARE, LONDON, W.C.1.

INDEX TO THE EPITOME FOR VOLUME I, 1934

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral; Heart and Cardiac; Liver and Hepatic; Renal and Kidney; Cancer and Carcinoma; Epithelioma, Malignant Disease, New Growth, Sarcoma, etc.; Child and Infant; Bronchocele, Goitre, and Thyroid; Diabetes, Glycosuria, and Sugar; Eye, Ophthalmia, and Vision, etc.

The Figures in this Index refer to the Number of the Paragraph, NOT the Page.

A.

ABASSI, A. F.: Diagnostic value of Tricoire's reaction in trachoma, 424
 Abortion. Erosion's reaction in biological diagnosis of, 523
 Abortion, curette, sharp, in treatment of, 81
 Abortion, habitual, treatment of, 18
 Abortion, induced, dangers of, 20
 ABRAHAMSON, D.: Relaxation of pelvic joints in pregnancy, 408
 ABRAHAMSON, J.: The heart in myxoedema, 375
 Abscess, brain, leaking, 253
 Abscess, cerebral, aspiration in, 50
 Abscess, paraneoplastic, and renal carcinoma, 71
 Abscess, pulmonary, intravenous injections of alcohol in, 340
 Abscess, subbrachial, 233
 Acid-fast bacilli. *See* Bacilli
 Acromioclavicular joint, dislocation of, 235
 Actinobacillosis in man, 104
 Actinomycosis, 482

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

Subacute Epidemic Hepatitis

IZARD, MAZIÈRES, and PONS (*Paris Méd.*, September 30th, 1933, p. 233) draw attention to a syndrome, hitherto undescribed and recently observed by them in the Toulouse district, characterized by febrile enlargement of the liver accompanied by changes in the blood picture and the serum, and appearing in a sporadic form or in small epidemic foci. Of the twelve cases observed, five occurred in a farm and a neighbouring brick kiln in the north of the department, three others in a family in the east-south-east, and four in a family in the neighbourhood of Toulouse. Of the twelve cases ten occurred at the end of August or beginning of September. Adults in the prime of life and children were affected. The blood changes consisted of an intense eosinophilia and positive Wassermann and Kahn reactions without there being any signs of syphilis. All other diseases, such as malaria, undulant fever, echinococcus disease, and amoebic hepatitis could be excluded by the appropriate tests. The immediate prognosis was good, as all but one recovered, but as the liver continued to be enlarged for several months after apparent recovery, a guarded outlook was indicated. It remained to be seen whether the condition described was a new special disease or a special variety of one already known.

2 Influence of Work and Sport on Heart Size

W. KNOLL (*Med. Welt*, September 23rd, 1933, p. 1345) denounces the oft-repeated verdict of Herxheimer that the heart is larger than normal in highly trained athletes. He gives figures showing that, in ski-runners, 60 per cent. have a normal transverse diameter, 30.5 per cent. less than normal, and only 9.5 per cent. greater than normal. W. THORNER (*ibid.*, p. 1346) investigated the influence of prolonged muscular exertion on dogs. He found that, compared with normal controls, these dogs had hypertrophied and dilated hearts and an increased stroke-volume. Progressive increase of the transverse diameter was observed radiologically. He argues that the same may occur in the human being. W. KAUFMANN (*ibid.*, p. 1347) writes on this subject from the radiological point of view. He believes that the transverse diameter of the heart may be increased by prolonged muscular exertion. Differences in size occur, and he recalls that the heart shadow is also some measure of the stroke-volume. This will account for the gradual diminution in size immediately after exercise. The picture given by the hypertrophied heart of the athlete is, he says, quite different from that due to hypertrophy, all chambers being proportionately increased in size.

3 Aortic Diastolic Murmur in Hypertension

L. GRAVIER (*Journ. de Méd. de Lyon*, September 20th, 1933, p. 565) refers to recent researches which prove that "functional" aortic incompetence can exist, and also that, even in organic regurgitation, the diastolic bruit may disappear. He states that this may be explained in slight cases by variations in blood pressure, by cardiac failure, with fall in blood pressure, or by simple changes in posture. There are also cases of "organic functional" regurgitation, in which the lesion is insufficient to produce a murmur. Gravier does not admit that these are due sometimes to enlargement of the aortic orifice. An attack of paroxysmal tachycardia or of complete arrhythmia may also abolish a diastolic murmur. In some cases treatment may assist the disappearance of the bruit, and result in a functional cure. The author quotes a case showing that an aortic diastolic murmur may disappear in spite of persistent hypertension. Further examples are cited in which, after disappearance of aortic diastolic

murmurs during life, necropsy has revealed serious valvular lesions. In such cases it is impossible to speak of "cures," but it can be stated that the functional consequences of the lesion are neutralized by valvular adaptations. It appears that this occurs only in aortic regurgitation following endocarditis—there is no record of such valvular adaptation in syphilitic aortitis. It is obvious in such circumstances that the fixation of the valves to the aortic wall by gelatinous exudate prevents the functional restoration of the valves.

4 Diaphragmatic Hernia and Angina Pectoris

MOSLER and HAAS (*Deut. med. Woch.*, September 1st, 1933, p. 1353) record an investigation on the frequency of hernia through the oesophageal hiatus and its possible relation to angina pectoris. In 1,500 radiographic examinations of the stomach this type of hernia was found forty-nine times, none of the cases being of the short oesophagus type. The average age was 61 years, and only two patients were under 50 years of age. The authors state that a dilated oesophageal ampulla needs careful distinction from hernia. Angina pectoris co-existed in twenty of the forty-nine cases, and was more frequent with the larger herniae. The cases were grouped into: (1) herniae the size of an egg or greater (nine cases, five of which had angina); (2) those the size of a walnut (eleven cases, five with angina); and (3) those the size of a cherry (twenty-nine cases, nine with angina). In one case there was also oesophageal dilatation and dysphagia.

Surgery

5 Supracondylar Fracture of the Humerus in the Young

A. BECK (*Zentralbl. f. Chir.*, September 23rd, 1933, p. 2242) states that conservative treatment has given him ideal anatomical and functional restitution in twenty-nine cases, treated in four years, of supracondylar fracture of the humerus of children; he is therefore averse from operative reposition and bone suturing. These cases had the common backward displacement of the lower extremity, and included three old unreduced fractures (nine to fourteen days). In old-standing cases Beck stresses the importance of securing correction, and of prolonged, patient manual extension (half an hour sometimes being necessary). The traction is applied in the direction of the long axis of the upper arm to the lower arm, which is held flexed to a right angle and pronated to relax the pronator and flexor muscles attached to the internal condyle. During the extension careful massage is performed. After reposition plaster is applied with the patient prone, the elbow at a right angle, and the forearm vertical. For a further eight or ten days the child is kept in bed in the same position, the splint being suspended from a hook. Plaster is worn for the following three or four weeks, and special treatment is unnecessary, free movement gradually returning with ordinary use of the elbow.

6 Age and Sex Incidence of Chronic Appendicitis

S. WINDER (*Nord. Med. Tidsskrift*, September 23rd, 1933, p. 1121) publishes a study of 209 cases of chronic appendicitis observed at the communal hospital of Ullevål in Oslo. He classifies them in three main groups: (1) chronic appendicitis with a history of one or more acute attacks, operated on in a free interval; (2) chronic appendicitis without a definite history of an acute attack, and without anatomical or functional involvement of the large intestine; and (3) chronic appendicitis associated with local or general involvement of the large intestine. Striking

features common to all three groups were the low average age (22, 23, and 26 years respectively) and the preponderance of female patients (81, 97, and 84 per cent. respectively). In an earlier study Widerøe found that the sex incidence of *acute* appendicitis was approximately equal (women 47 and men 53 per cent.). This striking difference in the sex incidence of acute and chronic appendicitis may possibly be explained by the preference shown by women for operations during a free interval. If this is so, the greater liability of women to suffer from chronic appendicitis is more apparent than real. A survey of the symptoms in the three groups showed that dyspepsia was not a characteristic symptom in any group, but was most common in the third group. The results of appendicectomy were good in the first group, less so in the others. According to this author, when the large intestine is involved appendicectomy should be only a link in the treatment, and if surgeons neglect the medical treatment of the colon, they must be prepared to find their operative results most disappointing.

7 Transurethral Prostatic Resection

G. J. THOMPSON (*Amer. Journ. Surg.*, September, 1933, p. 421) considers that this operation can be used in all cases of prostatic hypertrophy in which it is possible to pass an operating instrument. In a series of 205 cases operated on by the transurethral route the majority were beyond the sixth decade of life, and many were in extremely poor physical condition. The relief afforded in many cases of otherwise inoperable carcinoma was very encouraging, and urinary function was restored to many patients who had been wearing suprapubic tubes or leading a catheter life rather than undergo the risk of prostatectomy. The low mortality rate and good immediate results were found to justify the marked technical difficulties experienced in operating on the larger glands. In certain cases of badly infected bladders (with or without diverticula) a primary suprapubic operation was found necessary. Thompson fully describes the technique of the operation: in most instances the Braasch-Bumpus punch was used. In 89.5 per cent. of cases relief was afforded by one transurethral resection; in the remainder two, and sometimes three, resections were necessary. Severe post-operative haemorrhage after the tenth day occurred in 5 per cent. of cases and epididymitis in 8 per cent. The period required for complete healing was variable: when the resection was extensive it was usually a little less than three weeks. There were no deaths in this series, and a total of 236 cases have been operated on in a year without a fatality. As the material is comparatively recent it is too early for true recurrence to have developed, and at present only five of the series can be classed as cases of recurrence. Three of these had benign hypertrophy for which punch operations had been performed several years previously; the other two had carcinoma, and resection was performed a second time some months after the initial operation.

8 Tumours of the Testicles

A. PETERSON and W. E. COSTLOW (*Urol. and Cut. Rev.*, October, 1933, p. 720) record forty-one cases of tumours of the testicles in patients aged from 16 to 59. Pathologically the tumours were grouped as teratomas (mixed cell tumours) and seminomas (single cell tumours). The cases were classified in the following three groups: (1) Thirteen patients now living and free from clinical evidence of the disease, in whom no metastases were found on the original examination and upon whom orchidectomy only was performed, followed by prophylactic radiation with x rays. (2) Three patients alive and apparently free from disease, upon whom an orchidectomy was performed and who showed signs of recurrence. (3) Twenty-five patients who had died. In twenty-four of these orchidectomy had been performed, and in one orchidectomy and radical resection followed by varying amounts of radiation. Sixteen patients, therefore, were alive and free from disease for a time ranging from ten months to over ten years. Metastases might, the author points out, occur later.

Therapeutics

9 Malachite Green as a Skin Disinfectant

E. FIORINI (*Il Policlinico*, Sez. Prat., October 2nd, 1933, p. 1563) has carried out experiments to ascertain whether it is possible to replace tincture of iodine in the preparation of the skin for operation by something equally efficacious and less irritating. His main objections to iodine are that it is irritating to the surgeon's eyes and to parts such as the external genital organs of the patient, and that in persons whose skin is hypersensitive it sometimes leads to vesication, with the consequent danger of post-operative suppuration of the skin in the neighbourhood of the wound. Experiments made with malachite green show that this dye is devoid of these disadvantages, and that it is a powerful germicide when applied to the skin. Its activity in alcoholic solution increases with the concentration of the dye, and, within limits, with a decrease in the strength of the alcohol. After a number of trials, in which cultures were taken after varying times from skin which had been treated with malachite green and with iodine, the author concludes that the most satisfactory strength is a 10 per cent. solution of the dye in 40 per cent. alcohol. This solution has approximately the same germicidal activity as tincture of iodine without the objectionable properties of the latter, and is therefore recommended for trial by surgeons.

10 Treatment of Malignant Diphtheria

During the last two years A. STROË (*Arch. f. Kinderheilk.*, September 29th, 1933, p. 86) has observed a large number of cases of diphtheria and scarlet fever characterized by a necrotic or gangrenous condition of the fauces. Cultures of the throat in the cases of diphtheria yielded large quantities of *B. perfringens*, and an anaerobic coccobacillus, as well as diphtheria bacilli. As a result of his experiences in seventeen cases, Stroë concludes that in many instances malignant diphtheria is due to the association of the diphtheria bacillus with anaerobic organisms, and that unexpectedly good results may be obtained by the combination of diphtheria antitoxin and antiganrene serum from the onset of the disease.

11 Transfusion in Post-operative Thrombophlebitis

R. BOURG and LAVAND'HOMME (*Bruxelles-Médical*, October 8th, 1933, p. 1451) do not consider that post-operative thrombophlebitis is necessarily a contraindication to transfusion in chronic anaemia, and fully report two cases in which progressive cure attended this measure. Both patients suffered from chronic anaemia caused by repeated haemorrhages, due in one case to uterine carcinoma, in the other to a uterine fibroma. In both, thrombophlebitis of the iliac vein, with marked accentuation of the anaemia and deterioration in the general condition, supervened after total hysterectomy. Despite persistence of the extensive phlebitis, a transfusion of 250 to 300 c.cm. of citrated blood (3 grams of citrate), and 400 c.cm. of citrated blood (3 grams of citrate) with 100 c.cm. of physiological serum, were given to each patient respectively. This was the only treatment employed. Marked improvement in the haemic conditions and general state and in the phlebitic lesions rapidly ensued, and cure was progressively established. The authors assert that chronic anaemia predisposes to post-operative phlebitis, which results both from the blood dyscrasia and from the usual factors of operative traumatism and infection. The former is often but slightly evident, though many cases of uterine fibromata are accompanied by chronic inflammatory lesions of the adnexa. Infection, due to the intrauterine lesions, was the probable factor in the present cases. The dangers of this procedure result from three causes: incompatibility between the patient's and donor's blood, with consequent embolisms; marked increase of the blood coagulability after transfusion in phlebitis, a condition in which it is already greatly increased; and increased blood pressure due to the introduction of a large amount of fresh blood, which appears to increase the risk of embolisms.

Jan. 6, 1934]

EPITOME OF CURRENT MEDICAL LITERATURE

[To be continued 3

Dermatology

12 Toxic Action of Metals in Alepecia Areata

Metallic intoxication is considered by MAYER, Thromb., and KISSACKY (New York State Journ. Med., August 1933, p. 931) to play an important part in the production of alepecia areata. The similarity between the type of hairless patches produced by thallium and that of alepecia areata suggested that common metals might play a part in the production of the disease. Metals tend to accumulate rapidly in the reticulo-endothelial system, and the result of this transferred to sensitive nervous system produces various symptoms, notably abnormal local metabolic processes. Lead and cyano, and increased vascular permeability. Lead and arsenic are readily available for absorption from food, drugs, and liquids. In a series of 150 cases of alepecia areata, lead or arsenic was found in varying abnormal amounts in the hair, blood, or urine in as many as 75.75 per cent of cases. The laboratory data obtained seem to indicate that damage to the reticulo-endothelial system caused by common metals plays an important part in the production of alepecia areata. As a method of treatment of the disease it is suggested that all sources of metallic absorption, such as lead pipes, and the habit of spraying of toothbrushes with arsenic, should be avoided. It is stated that metallic elimination may be aided by the administration of 1 to 3 grams of pure crystalline sodium thiosulphate three times a week.

13 Enterococcus Dermatitis in Infants

C. CHENE (Thèse de Paris, 1933, No. 146), who records an illustrative case, seven of which are normal, states that the dermatitis on the buttocks of infants, which is regarded as a form of erythema, is due to the enterococcus. Treatment by an anti-enterococcus vaccine without any local treatment produces a rapid and complete cure not only of the skin condition, but also of the digestive disturbance accompanying the dermatitis. The intradermal, buccal, or rectal route may be employed, the buccal being the most convenient. Vaccine treatment may often be accompanied by prescription of a suitable diet.

14 B. coli Vaccine as a Local Application

H. ROHR (Munch. med. Woch., September 22nd, 1933, p. 1476) discusses dermatological conditions of the perianal region. He considers that the eczematous state so commonly seen there starts as pruritus; the patient then scratches, producing excoriation which becomes infected with *B. coli* from the rectum and leads to eczema. He has treated such cases with "posterior-coil" vaccine. This may be obtained as an ointment or as a suppository. In his hands this form of therapy has given good results in what is usually an obstinate condition. Local applications of vaccine have the support of Besredka's well-known work on tissue immunity.

15 Thrombophlebitis Migrans

A. BESCHKE and A. JOSEPH (Klin. Woch., September 23rd, 1933, p. 1483) describe the case of a healthy man of 43 years suffering from recurrent thromboses in the more superficial veins of both legs, which had resulted in a high degree of venous stasis. All the usual forms of treatment were tried without improvement. Eventually 3 grams of ung. hyalarg. were injected daily, and this was rapidly followed by improvement, no further thromboses occurring.

16 Animal Carriers of the Ringworm Fungus

A. M. DAVIDSON and P. H. GREGORY (Canadian Med. Assoc. Journ., September, 1933, p. 242), discussing the transmission of ringworm infection from animals to children, state that in Winnipeg, while more than half the cases of microsporon ringworm were due to the human fungus (*Microsporon audouinii*), two-thirds of the separate outbreaks were due to *M. felinum*, which causes disease

mainly in cats, dogs, and horses. They were able to trace infection definitely from a kitten to a boy, and from the boy to a previously uninfected cat. It was found that the hair of cats infected with *M. felinum* exhibited a fluorescence in ultra-violet light similar to that found in infected human hair, and the extension of the fluorescence test for the detection of microsporon infection in cats and kittens is suggested as a practical prophylactic measure. This should apply also to pet animals which have been in contact with unexamined children. The authors find that apparently healthy cats may yet be carriers.

Obstetrics and Gynaecology

17 Foetal Danger Signs during Labour

A. MAYER (Munch. med. Woch., October 6th, 1933, p. 1535), discussing two cardinal signs of impending danger to the foetus—lowering of the foetal heart rate and passage of meconium—reviews recent observations which have shown that a fall in the heart rate of below 100 in the intervals between uterine contractions—especially if this rate persists for forty minutes, the child will, it is stated, probably die, though the author quotes two cases of retarded foetal heart rate in which the outcome was successful. The second danger sign—escape of meconium—must be differentiated from green-coloured amniotic fluid due to previous passage of meconium. Any solid masses indicate that evacuation has been recent, and that asphyxia threatens. While stressing the danger of these signs, Mayer believes that in many cases in which instruments are applied on account of indications of foetal danger, delivery would have occurred normally, and that, unless the danger signs are definite and persistent, reasonable delay is preferable to precipitate interference.

18 Treatment of Habitual Abortion

H. STÄUBLE (Zentralbl. f. Gynäk., September 23rd, 1933, p. 2226) discusses the treatment of repeated abortion in the same patient, in the absence of syphilis, trauma, or disease of the genital organs. He has been able, in many cases of these habitual abortions, to secure the carrying of the next pregnancy to term by injecting at fourteen days' intervals, subcutaneously or intramuscularly, 10 cent of serum from healthy pregnant subjects. The treatment is based on the hypothesis that normal pregnancy serum contains bodies which decrease contractility of the pregnant uterus. That these are derived from the corpus luteum is suggested by the antagonism which Knäus has described between the anterior pituitary lobe and the corpus luteum, and also by Reynold's experimental demonstration that injection of urine from pregnant subjects diminishes uterine contractions.

19 Diathermy in Chronic Endocervicitis

A. STÄUBLE (Arch. Uruguayos de Med., Cir. y Esp., September, 1933, p. 351), having observed fifty cases treated by diathermy, states that cure can almost always be effected if simple precautions are observed. Anaesthetics are unnecessary, and, except for drying the vagina with gauze, the patient need not be prepared. Stäuble uses a high-frequency apparatus furnished with a rheostat which is set at 21 or 3. The current is controlled by a mercurial interrupter. He ignores the milliamperemeter owing to its too constant variations. The active pole, terminating in a metal electrode, is introduced into the cervical canal until it reaches the os internum. The current is turned on only for a few seconds. The appearance of the tissues around the os externum indicates the effect produced in the canal. They become of a pearly yellow hue, which soon loses its lustre and changes to a dull grey. When this is seen the electrode is withdrawn and the parts touched with a pledget soaked in antiseptic

oil. The patient is allowed up, and the vagina is irrigated with Carrel-Dakin solution for some weeks. The cervical canal is dilated periodically with a soft rubber bougie for some months. The new mucosa is smooth, soft, non-fibrous, and contains but few glands. The treatment is contraindicated by pregnancy, corporeal endometritis, all acute genital or perigenital affections, neoplasms of the cervix (suspected or outstanding), or the presence of the catamenia. Chronic adnexitis, if quiescent, offers no contraindication, but the patient should keep her bed for some days. The colposcope—a kind of binocular microtelescope affording a good view of the cervix at from 10 to 15 cm. from the objective—is a very valuable help when observing the lesions and the progress of cure.

20 Dangers of Induced Abortion

P. KÜHNEL (*Ugeskrift for Læger*, September 21st, 1933, p. 1013) publishes a study of 200 hospital cases in which, since 1919, abortion was induced on medical grounds. The most common indication for induction was pulmonary tuberculosis (101 cases). There were two operative deaths; severe hæmorrhage occurred in at least 8 per cent., and infections in 18 per cent. Dilatation of the cervix in 158 cases led to tears in eighteen, and the percentage associated with accidents was 22. Among these "accidents" are perforation of the uterus, which occurred in two, and possibly three, cases, Hegar dilatation being responsible. Classification, according to the operation was undertaken by the professor in charge of the hospital or by one or other of his assistants, showed how much the outcome of the operation depended on the dexterity and experience of the operator. In the face of all the mishaps, and even misfortunes, experienced in these 200 hospital cases, the author asks what would have happened to them in the hands of unskilled operators working under less satisfactory sanitary conditions. Kühnel submits his material and the conclusions drawn from it to those of his colleagues who, in discussions at medical meetings, treat the induction of abortion with "the easy airiness of ignorance," and imply that such an undertaking is simple and safe.

Pathology

21 B. coli Septicæmia in a Newborn Child

F. ATHENSTÆDT (*Zentralbl. f. Gynäk.*, September 30th, 1933, p. 2302) records a case of *B. coli* septicæmia in the child of a mother who had had a severe attack of pyelitis just before term. The infant appeared well until the third day, but died on the fourth day, six hours after the appearance of a hypogastric cellulitis which respected the navel. At necropsy *B. coli* was found in the meninges, heart, blood, liver, and peritoneum, and the serous membranes were inflamed. Transplacental transmission of *B. coli* has, the author states, been demonstrated in other cases, including one of Sennewald in which delivery by Caesarean section in a patient with pyelitis and ileus gave a stillborn foetus having *B. coli* in blood from the heart. Athenstædt points out that *B. coli* sepsis in the newborn has an unfavourable prognosis, and he recommends injections of maternal blood.

22 Humidity in the Propagation of Diseases

A. AIMES (*Rev. d'Hyg.*, October, 1933, p. 614), in a discussion of this problem, concurs with Trillat in his belief that the composition of the air and the gases diffused through it acts upon the microbic contents, and that the hygrometric degree of the air is important in bacterial diffusion and multiplication. Trillat has shown that the fine vesicular droplets of atmospheric aqueous vapour form a veritable culture medium. Dry dusts are arrested and fixed by the mucus of the nose or pharynx and by the vibratile cilia of the trachea; droplets, owing to their spherical shape and superficial tension, traverse the mucosa without adhering to it.

Though not always pathogenic if the air is pure, humidity renders the subject more susceptible to external conditions by reducing the peripheral circulation and modifying conductivity to these conditions; this is said to be especially true of "cold" humidity. It is stated that rain, though purifying the atmosphere, has also a pathogenic action. Enteric fever is more frequent in rainy periods following dry ones, while the morbidity of scarlet fever, measles, and diphtheria, and the mortality in tuberculosis, are greater in wet years. Nugge has noted the frequency of influenza and respiratory diseases during wet seasons. Fogs, especially in towns and manufacturing centres, have a pathogenic action owing to the deleterious gases they contain, and the recent outbreak in the valley of the Meuse is cited as an example of this. Atmospheric ozone plays a protective part against the harmful action of solar rays, in particular the ultra-violet. Its exact action is undetermined; it, however, purifies the air by ridding it of bad odours, putrid gases, and volatile organic matters, and is thus indirectly bactericidal.

23 Iodine Content of the Blood

According to G. M. CURTIS, C. B. DAVIS, and F. J. PHILLIPS (*Journ. Amer. Med. Assoc.*, September 16th, 1933, p. 901) the iodine content of human blood is an index of thyroid function. Normally about 0.012 mg. per 100 c.cm., it is raised in thyroid hyperfunction and lowered in hypofunction. It is always elevated by any form of thyroid medication. In exophthalmic goitre it was found to range from 0.016 to 0.04, and in cases of congenital cretinism or post-operative myxoedema from 0.007 to 0.011 mg. The effects of treatment in these cases were indicated by corresponding changes in the blood iodine figures. After an adequate thyroidectomy, followed by the usual abatement of the characteristic symptoms together with the subsequent fall in the basal metabolic rate, the blood iodine was found to fall to a low normal rate, in the absence of any iodine medication. In patients with a non-toxic goitre the iodine content is usually within the normal range. In most diseases other than those of the thyroid gland the iodine figure is normal, but in acute severe infections, such as septicæmia, it is raised, as also in lymphatic leukaemia. A rise occurs also in the early stage of menstruation. The author believes that the level is maintained by thyroid action, and that its estimation has valuable diagnostic and therapeutic possibilities. The urinary iodine content was found to rise similarly with increased thyroid activity or iodine medication.

24 Freund Dermal Reaction in Malignant Disease

J. CHOLEWA and ST. CERNELC (*Wien. klin. Woch.*, September 1st, 1933, p. 1072) review the evidence that cancer is a disease in which local neoplasia is accompanied by general biochemical changes which make possible the serological diagnosis of the condition. Freund has found in the serum of non-cancerous patients substances which cause lysis of tumour cells. These lysins are absent from the blood of gravid women and patients with malignant disease. These substances have a high degree of specificity; thus serum from a patient with carcinoma will still contain lysins for sarcoma, and vice versa. The lysins appear to be elaborated in the bowel. In addition, the serum of cancer patients contains a substance which protects the cancer cells against the lysis by the serum of non-cancerous patients. Associated with these serological changes are changes in the blood chemistry: the blood sugar is raised in carcinoma and the peptone content of the serum in sarcoma. Freund has isolated from the intestine a "carcinoma fatty acid" which gives a positive dermal reaction in carcinoma. Cholewa and Cernelc, the present authors, have used this reaction in fifteen patients with carcinoma and twenty-seven non-cancerous controls. All the former gave a strongly positive reaction; twenty-five of the controls were negative, and of the two who gave positive reactions one had diabetes mellitus, and thus a hyperglycaemia similar to that found in carcinoma, and the other was thought possibly to have a symptomless carcinoma causing wasting.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

25 Undulant Fever in a Child

W. HUTHWAINE and K. ELLIOT (*Arch. f. Kinderheilk.*, September 26th, 1933, p. 635), who record a personal case, illustrate the rarity of undulant fever in early childhood by the fact that they could find only thirty cases on record. In almost all the cases the diagnosis was established by the agglutination test, and in some instances by the complement fixation test. In several cases the children showed either no clinical evidence of disease or no symptoms suggestive of undulant fever. In the authors' case, which occurred in a well-nourished 3½ year old child, the disease was due to consumption of raw milk. The child was admitted to hospital with the diagnosis of septicaemia of bacterial origin. Death took place after six months' illness, which was complicated by nephritis and pneumonia. The diagnosis was established by the agglutination test, for the characteristic undulant fever developed. The case was remarkable for being the first in which *B. abortus* was cultivated from the blood in a child under the age of 5 years.

26 Endemic Typhus Fever

A. C. KENNERLY and J. E. F. RILEY (*New England Journ. Med.*, September 14th, 1933, p. 542) record their observations on ten cases of endemic typhus fever admitted to the Beth Israel Hospital at Boston from 1929 to 1932 inclusive. The cases corresponded in all essential features to the condition known as Brill's disease. All the patients were residents of separate areas of Boston or its suburbs, and had lived in the United States for many years. In no instance was more than one person in a household affected. Six of the ten cases occurred during the warm months of the year. A positive Weil-Felix reaction was obtained in eight cases. In several cases there was a slight rise in the total protein content and number of leucocytes in the spinal fluid during the febrile period. The writers conclude that there is a rather widespread reservoir of the disease in and about Boston, and that unrecognized cases are occurring in the community.

27 Colds in Arctic Regions

J. FRIS (*Tidsskr. f. d. Norske Lægeforen.*, September 15th, 1933, p. 973) has investigated the incidence of catarrh of the upper respiratory passages and influenza-like conditions in Long Year town, latitude 78°, in Svalbard (Spitzbergen), where he has been attached since the summer of 1930 as medical officer to a coal mine. The community consists of about 440 workers, women and children bringing the total up to about 550. They are completely isolated between the middle of October, when the last boat leaves Svalbard, and the middle of May, when the first boat of the year arrives. Records kept of the incidence of catarrhal infections throughout the year showed two main peaks. By far the highest peak, both in 1930 and in 1931, occurred early in the summer and coincided with the arrival of the first boat of the season. A curious observation was the frequency, on these occasions, of colds among the new-comers; among fifty-one newcomers from the first two boats, there were as many as seventeen who caught colds on coming to Svalbard. The residents also suffered greatly on the same occasions. During the remainder of the summer there would be a decline in the incidence of colds, followed by a second peak in the autumn, coinciding with the departure of the last boat. This peak may be connected with the increased interchange of contacts due to the departure of the last boats. After this autumn peak there was a gradual decline in the incidence of colds throughout the

winter, but at no time was the community completely free from colds. Having obtained a stock of anti-cold vaccine from the State Institute for National Hygiene in Oslo, Fris administered it as a prophylactic to those of the community who did not object to it. The objections ceased to continue. The 165 persons who were treated did not, however, appear to be more immune to colds than the controls.

28 Recurrent Herpes Zoster

H. GERHART (*Munch. med. Wochs.*, September 15th, 1933, p. 1437) gives reasons for the belief that this disease occurs more frequently than has been hitherto believed. In recent years numerous recurrences have been reported; one medical man had eleven attacks during his own life, always in the left gluteal region. Relating his own personal experience, the author states that since 1928, after any attack of zoster, he has suffered from herpes simplex. In addition to this he had an attack of right cervical herpes zoster. The diagnosis was confirmed by a colleague. In 1931 he had another attack, whilst a colleague had an extraordinarily severe attack of varicella and left cervical herpes zoster. In the spring of 1932 the author had a sudden attack of severe (right) herpetic neuritis, followed next day by typical herpes zoster, which healed, leaving characteristic pigmented scars.

Surgery

29 Fracture-dislocation of Mandibular Condyle

K. POST (*Zentralbl. f. Chir.*, September 9th, 1933, p. 2118) states that this injury is more common than is generally recognized, and pleads for conservative methods of treatment, which were successful in spite of insufficient anatomical correction near the temporomandibular joint in a case here described. He recommends restitution of dental alignment by splinting, and the allowance of a moderate degree of motion at the condyle, and finds that a good functional result is obtained by attending to the body of the mandible and awaiting natural cure of the fracture-dislocation of the condyle. Operative reposition, bone suture, and excision of the condyle are, he believes, unnecessary.

30 Radiology of Femoral Head in Infants

Stating that the epiphyseal nucleus of the femoral head becomes calcified and demonstrable in radiographs only after the third year of age, and that the equal opacity of the head and the surrounding tissue makes radiodiagnosis failures frequent, J. CORRY (*Le Scalpel*, September 23rd, 1933, p. 1482) finds insufflation of air into the articular capsule of value. By this procedure radiographs reveal the exact contours of the cartilaginous bones, the articular contours, and those of the contained organs with their relations to each other. He uses a vaselined sterilized 10 c.cm. Luer syringe and a needle with a stylet 5 cm. long and 1 mm. thick, having a rather short bevel. After locating the trochanter, femoral artery, Fallopien arch, anterior superior iliac spine, and "right anterior muscle," he introduces the needle vertically to the head midway between the femoral artery and the prominence formed by the muscle, until it meets a hard body; it is then slightly withdrawn and directed more obliquely to penetrate the capsule. One c.cm. of air is now injected. If great resistance is met, the needle has entered cartilage; if there is none, the muscle or cellular tissue has been penetrated. Slight resistance indicates penetration of the capsule, and 5 to 10 c.cm. of air are then injected without force to avoid

escape of the air through the puncture. The needle is now withdrawn, the piston being kept under pressure before taking the plate. In some cases this technique is impossible, and the needle must be introduced laterally outside the muscle, along the neck, and into the capsule between the cotyloid roof and the head. This measure is without danger, necessitates no anaesthetic, and causes no after-effects. It is indicated in cases of traumatism (epiphysiolysis), malformations (congenital luxations), and bone diseases (rickets, achondroplasia, osteochondritis, and coxa vara).

31 Perforated Gastric and Duodenal Ulcer

L. ROUSSELIN (*Lyon Chir.*, September-October, 1933, p. 543) gives a comprehensive review based on sixty-six cases operated on for perforated gastric or duodenal ulcer. Although the condition is found at any age, the highest proportion of cases occur in middle life, and usually in men. In the series reported only three cases occurred in women. Patients may be divided into three classes: those in whom the perforation is the first indication of any gastric lesion, those who have had symptoms for a few days or weeks, and those—comprising the majority of cases—who have had gastric trouble for several months or years. In the last group the perforation usually occurs during a particularly acute attack. The most common site of perforation is the duodenum, where it occurred in fifty-one of the reported cases. The remaining cases were found in the pyloric region of the stomach and on the lesser curve in equal frequency. The size of the perforation may vary from a pin's head to a franc; the smallest are found in the duodenum and the largest in the stomach. From an operative point of view the size of the opening is of little importance, as it is usually surrounded by a zone of induration which can only be sutured with difficulty. The mortality varies according to the site of the lesion. Out of fifty-one duodenal perforations there were thirteen deaths (25 per cent.), there were seven pyloric perforations with four deaths (57 per cent.), and seven perforations of the lesser curve with five deaths (71 per cent.). The operative treatment should be as simple and quick as possible. Suture of the perforation alone is the best procedure, and it is only when the duodenum is narrowed that a gastro-enterostomy should be added. Drainage to the pelvis was instituted in all but one case. Emphasis is laid on the importance of early operation. When this was carried out in under six hours the mortality was only 17 per cent., whilst over twenty-five hours the mortality was 90 per cent.

Therapeutics

32 Control of Diphtheria Epidemics

M. J. HOLMES (*Med. Journ. of Australia*, September 16th, 1933, p. 366) records an investigation of children during an inter-epidemic season of diphtheria. He took throat swabbings from patients exposed to diphtherial infection, and from others. The results showed that exposure to definite infection had not greatly affected the percentage of positive swabs, but that in the exposed group there were many who were carriers of virulent organisms, whereas in the non-exposed group no virulent organisms were present. The necessity of following up swabbing with virulence testing is, he argues, obvious. It is suggested that the frequency and massiveness of the infection and the physical condition of the child may be as important as the virulence of the organism in the determination of the development of the clinical manifestations of the disease. If the dose, although virulent, is small, a child who is apparently susceptible and harbours the organisms may be able to develop immunity in time to forestall development of the disease. The value of Schick testing and active immunization against diphtheria during an epidemic is emphasized by C. S. BARBOUR (*ibid.*, p. 363), who describes a campaign carried on in Port Pirie in 1932. The occurrence of the epidemic

destroyed public apathy, and consent for testing and immunization was readily obtained. Barbour considers that it is possible to dispense with a control for the Schick test if time is a factor of importance. Full injections of anatoxin confer absolute immunity on Schick-test standards in 90 per cent. of cases, and an increased degree of immunity in the remainder. Even small doses cause the development of some immunity, but it is not until doses of 0.1 and upwards are reached that the immunity is appreciable with only two injections. The author adds that it may be expected that anatoxin will give rise to no general reaction, and to no local reaction of serious import, provided that the dosage is regulated by the previous skin test. In young children, in whom immunity is most desirable, anatoxin sensitiveness is exceptional.

33 "Solvitren" in Graves's Disease

H. GEUTING (*Med. Klinik*, September 22nd, 1933, p. 1316) has treated a series of cases of Graves's disease by injection of "solvitren," a proprietary preparation of decolorized animal blood. To avoid anaphylaxis, injections of the drug prepared alternately from sheep and ox blood are used. The rationale of the treatment, which was first advocated by Bier in 1901, is that whole blood is the most efficacious of all polyglandular products, and that the body can abstract from it just those hormones that it needs. Geuting claims remarkable success with this form of therapy—great relief, objective and subjective, being conferred upon all his cases. Weight was regained, basal metabolism was reduced, and tachycardia diminished. None of his twenty-three cases required operation after a course of this treatment.

34 Gold Salts in Pulmonary Tuberculosis

German and French authorities have recommended gold salts in oily suspension in the treatment of pulmonary tuberculosis on the grounds that they are better tolerated, and that the action of the salt is thereby prolonged. Dumarest and Mollard have especially advocated solganal B—particularly in debilitated subjects—in those intolerant to other auric preparations, and in patients needing very active treatment. A. GIRAUD (*Presse Méd.*, September 20th, 1933, p. 1456), who is not wholly of this opinion, gives details of four cases which failed to respond to the therapy. Lumière has stated that when solganal B is injected in oily suspensions an intense osmosis occurs in the pocket caused by the injection; the gold salt is rapidly absorbed by the transuded liquid, the oil alone remaining at the injection site, which is innocent of gold after twenty-four hours. Feldt, the discoverer of solganal B, maintains that the particles of this drug are resorbed by the phagocytes around the injection, are carried by them to the lymphatic circulation, and stored in the ganglia; simple absorption does not occur. Without concurring in either of these opinions, Giraud believes that the results in his and other recorded cases show that extreme care should be exercised in employing gold salts in oily suspension in the types of cases named by Dumarest and Mollard, as the lower toxicity of these substances in oil has not been definitely demonstrated.

35 Symptomatic Treatment of Asthma

M. ANGLADE and O. GAUDIN (*Bull. Soc. de Théor.*, October 9th, 1933, p. 196), who record five personal cases in patients aged from 23 to 57, state that some individuals show an intolerance to ephedrine characterized by tremor, vertigo, and nervous irritation. They have found that these symptoms can be prevented by combining ephedrine with papaverine and codeine in the following proportions: ephedrine hydrochloride 0.01, papaverine hydrobromide 0.03, and iodide of codeine 0.02 gram. In spite of the prolonged use of this mixture no unpleasant symptoms have arisen apart from dryness of the mouth and a slight tendency to somnolence in a few cases. The mixture is also of value in attacks of spasmodic coughing, which are often very difficult to treat successfully.

Anaesthetics

35 Intravenous Anaesthesia with Sodium Evipan

J. GORONOFF (*Semana Médica*, August 10th, 1933, p. 408), writing from St. Hedwig's Krankenhaus, Berlin, states that sodium evipan (pentamethyl C-Cyclohexyl methyl barbituric acid) is an ideal general anaesthetic inasmuch as, free from all toxicity, and without upsetting the patient, it produces instantaneous and profound sleep, which renders possible all kinds of surgical manipulations, is specific and completely eliminated, has no disastrous after-effects, and may be readily prepared and administered by any practitioner. It is a white powder, highly soluble in distilled water. A 10 per cent. solution is employed, of which the dose, according to the weight of the patient, is from 3 to 10 c.c.m. In his own practice the writer is also guided by the general condition of the patient, believing that nervous subjects require rather more, while the debilitated require less, no matter what their weight may be. The solution may be injected into any vein. There is no "stage of excitement." The corneal reflex disappears almost at once, while the pupillary light reflex persists throughout the anaesthesia. Relaxation of the mandible is a sign that a sufficient amount of the anaesthetic has been administered. The needle may then be withdrawn from the vein if the operation does not require a prolonged course. Complete anaesthesia after a single dose lasts from fifteen to twenty minutes. The reappearance of the corneal reflex is the earliest indication of the return to conscious life. There are no contraindications. The writer's personal experience is confined to its employment in operations on the genitourinary system, which include hyperaesthetic prostaticectomy, ureterectomy, castration, and the coagulation of vesical polypi by diathermy.

37 Pre-narcosis by Morphine and Paraldehyde

B. B. GARFITT and E. GUTTENBERG (*Med. Journ. of Australia*, July 8th, 1933, p. 46), commend morphine, paraldehyde, and hyoscine in suitable doses as basal narcotics for operations under local anaesthesia. They find also that morphine and paraldehyde, as a preliminary to general anaesthesia, are useful in relatively short operations, and tide the patient over the painful recovery period. An enema is given the night before the operation, and any necessary sedative administered to ensure peaceful sleep. One hour before the operation a hypodermic injection of morphine (1/4 grain) and hyoscine (1/100 grain) is given. Fifteen minutes later paraldehyde (0.5 drachm for each stone in weight) is dissolved in ten times its volume of normal saline solution and injected slowly into the rectum. Almost invariably the patient falls into a deep sleep before the injection has been completed, and the subsequent induction of anaesthesia is easy. At the end of the operation the patient returns to the ward still asleep, and remains so for one to four hours. In local anaesthesia much less cocaine or novocain is required. The authors noted a decided and definite drop in the blood pressure in all cases; this places certain cardiac patients—for example, those with coronary sclerosis—among the group of risky subjects for whom such pre-narcosis is undesirable. In 143 cases the authors had only one death, and in this case there was gross tuberculous involvement of the larynx, with obstruction to breathing, tracheotomy having to be performed. The patient died from respiratory failure, having an associated tuberculous and bronchiectatic involvement of the lung, and asthma.

38 Ethyl Chloride: A Statistical Inquiry

S. HORNEMAN (*Ugeskrift for Læger*, October 19th, 1933, p. 1145) has addressed a list of questions about ethyl chloride to 150 Danish hospitals, and has received 133 answers. It was used as a general anaesthetic in 117 of the 133 hospitals which replied. The replies dealt with 76,000 inductions of anaesthesia in which ethyl chloride

was used by itself or in preparation for another anaesthetic. In addition to these 76,000 recorded cases, there were many thousand other cases which had checked record in the hospitals which replied. Only two anaesthetic deaths were recorded. As for alarming collapse, there were twenty-six hospitals which had never observed it, and fifteen which had each had one case of collapse after ethyl chloride anaesthesia. There were ten hospitals with a couple of such cases each. In several of these cases the patients were children. There were forty-nine hospitals in which ethyl chloride anaesthesia was employed as frequently as before, forty-six in which its employment had risen, and seventeen in which it had diminished. All the hospitals employing ethyl chloride gave it on an open basis. In thirty-three hospitals both the drop and the spray method were employed, in thirty-three only the spray, and in fifty only the drop method. In only half a score of hospitals was ethyl chloride administered for five minutes or longer at a time. Undertakings requiring a longer interval were usually dealt with by a transition to ether. Summarizing his impressions from this inquiry, the author insists on the need for a very wide awake anaesthetist. It cannot be claimed for this anaesthetic, nor, for that matter, for any other given by inhalation, that it is perfectly safe. Yet, with only two deaths in this immensely large material, the risks of a fatal issue would seem to be exceedingly small, particularly if very young children are excluded. The author sees no reason why ethyl chloride should be given up as a general anaesthetic.

Obstetrics and Gynaecology

39 Pregnancy after Removal of both Tubes

N. P. WEHRATSKY (*Zentralbl. f. Gynäk.*, August 18th, 1933, p. 1941) records the case of a woman in whom the gravid left Fallopian tube was removed, with a wedge of the uterine cornu, to which the left ovary was sutured. The right tube, it was noted, was absent as the sequel of a previous operation for right tubal pregnancy. A normal uterine pregnancy followed the second operation, and the child was born at term, but died at the age of three months. Wehratsky states that eleven cases have previously been described of uterine pregnancy after ablation of both tubes; he alludes to a case of Zangmeister's in which a two months' uterine abortion, and later a spontaneous delivery at term, occurred.

40 Remote Prognosis in Eclampsia

A. OLSEN (*Ugeskrift for Læger*, September 21st, 1933, p. 1019) has investigated the subsequent careers of the women who, since 1910, had been treated in a maternity home where they had suffered from eclampsia or "eclampsism" (threatened eclampsia, with albuminuria, high blood pressure with or without oedema, headache, disturbances of vision, and drowsiness). In 102 of the 150 cases of eclampsia, information was obtained as to the subsequent fate of the patients. Among the 102 eclampsia patients were forty-nine who had subsequently undergone a total of eighty-two pregnancies, of which fifty-nine of the confinements had been uncomplicated. Among the seventy-eight eclampsism patients were twenty-nine who had subsequently become pregnant, giving a total of fifty pregnancies, with twenty-six uncomplicated confinements. The author brings up his total of post-eclampsia and post-eclampsism pregnancies to 175 by adding forty-three cases in which the patient had suffered from eclampsia, but not in his hospital. From this total of 175 he subtracts two doubtful cases and another eighteen because the pregnancy terminated in abortion within the first three months—that is, before a recurrence of eclampsia could have been expected. Among the remaining 155 pregnancies there were only ten cases of eclampsia or eclampsism. From Olsen's work emerges the remarkable observation that the patients who had had eclampsia had, on the whole,

subsequently fared better than those who had suffered from eclampsia. Of the 160 children, 139 (87 per cent.) were born alive and well, fifteen (9 per cent.) were born dead or died soon after birth, and six (4 per cent.) were classed as abortions. The author concludes that a history of eclampsia or eclampsism in a previous pregnancy does not by itself justify the induction of abortion.

41 Resuscitation in Neo-natal Asphyxia

E. SHUTE and M. E. DAVIS (*Canadian Med. Assoc. Journ.*, September, 1933, p. 252) discuss the methods of treating asphyxia in the newly born, with special reference to that due to narcosis following the administration of morphine to the mother. In one year they had a series of 320 infants delivered after such morphine injections, and found in 120 of these some degree of narcosis, deep in twenty-five. Six infants were apnoeic for over twenty minutes, and in one the respiration did not become normal for thirty-five minutes. All six infants survived, and subsequently appeared to be healthy. In thirty-six instances resuscitation was brought about by means of various mixtures of carbon dioxide and oxygen, but the authors found that pure carbon dioxide, followed by pure oxygen for very short periods of time, was much the most effective procedure. For general clinical use they recommend a 10 to 30 per cent. mixture of carbon dioxide in oxygen, to be followed by pure oxygen. They state that this mixture is not dangerous if used intelligently, and requires only very simple equipment. They emphasize the point, however, that such gases should not be used for longer than is necessary to initiate adequate respiration. In cases of mechanical obstruction the most effective method for clearing the air passages is the tracheal catheter. With this in place, the chest may be gently and rhythmically compressed to stimulate respiration. Violent methods are apt to be harmful. Insufflation can also be performed through the catheter, using minimal pressures, the operator's cheeks and not his chest muscles being the agents of force required.

Pathology

42 Determination of Non-Protein Nitrogen in the Blood

C. A. DALY (*Journ. Lab. and Clin. Med.*, September, 1933, p. 1279) points out that in the Folin method of determining the non-protein nitrogen content of the blood it is very difficult to avoid the separation of the silica from the glass during the long period of digestion. Heating the acid mixture rapidly obviates this, to some extent, but requires careful regulating of the flame, and there is a possibility that the oxidation process may not be complete. In Folin's original directions the period of digestion is excessive for practical purposes, and the best results are obtained by stopping the process as soon as the brown appearance of the mixture is replaced by a light green colour. When sulphuric acid with hydrogen peroxide or potassium persulphate is used for the digestion mixture, a white or yellow precipitate of tungstic acid nearly always appears, either during the digestion or when water is added. This acid precipitate is soluble in the alkaline Nessler solution, but the reagent itself is affected by the process of solution. Daly describes a modification of the Koch method for determining the blood non-protein nitrogen content, which is claimed to be more satisfactory, and to give accurate results. Gum ghatti and sodium citrate are used to prevent the precipitation of the colour reagent when solutions turbid from tungstic acid are Nesslerized. The digestion mixture is made up with hydrogen peroxide. It contains 45 per cent. sulphuric acid, and the Nessler solution is diluted so that 15 c.cm. will give the same final alkalinity as 12 c.cm. of the original reagent. A change in the technique becomes necessary, owing to this dilution. The nitrogen solution in the ignition tube (diluted to 35 c.cm.) and the Nessler solution are poured simultaneously into

a large beaker to mix, whirled round, and then poured back into the tube. In this way the two solutions are more intimately mixed, and there is less danger of turbidity. It is important for the solutions to be at room temperature when Nesslerized, since a higher temperature encourages precipitation. The author believes that this modified method of testing for non-protein nitrogen promises to be the most satisfactory one for routine use in the clinical laboratory.

43 Read's Formula for Basal Metabolism

H. NEUMANN (*Klin. Woch.*, September 16th, 1933, p. 1444) examines the range of application of the well-known formula of Read for basal metabolism. A uniform opinion of the value of this formula in clinical work has not hitherto been reached by the many workers in this field. Read, and later Umber and Rosenberg, concluded that in 90 per cent. of cases the formula gave a result within 20 per cent. of the values obtained by gas analysis. Other workers have reported even more favourable correspondence. The majority agree, however, that with increasing basal metabolism the formula becomes less reliable, so that it has been suggested that it is valuable only in borderline cases, and will detect slight deviations from the normal with astonishing accuracy [Bertheau]. Other workers have definitely condemned the formula, and Gale and Gale (*Lancet*, 1931, i, 1287) proposed the modified expression, $B.M.R. = (Pulse + Pulse Pressure - 111)$; but even this has not been found satisfactory. The present author, having access to a large metabolic material, was able to compare the results of B.M.R. determinations with Knipping's apparatus with those derived by Read's formula. Eighty-two cases were examined in this way, 48 per cent. having a metabolic rate over + 20 per cent., and 32 per cent. one of over + 30 per cent. In 72 per cent. of the cases the difference between the formula and the respiratory gas analysis exceeded 5 per cent.; in 55 per cent. it exceeded 10 per cent.; in 34 per cent. it exceeded 15 per cent.; in 22 per cent. it exceeded 20 per cent.; and in 8 per cent. it exceeded 30 per cent. (these figures represent the absolute, not percentage, differences). It was found in this series also that with increasing B.M.R. the error of the formula became greater. Further, a negative value on the gas analysis was not necessarily accompanied by a negative value on the formula. Calculation of the Gale formula in this series gave rather worse results than did that of Read. In conclusion, the author finds that in the important critical cases between 10 per cent. and 30 per cent. the Read formula is unreliable, and that as a clinical substitution for gas analysis it is without value.

44 Amniotin in Experimental Diabetes

B. O. BARNES, J. F. REGAN, and W. O. NELSON (*Journ. Amer. Med. Assoc.*, September 16th, 1933, p. 926) found that glycosuria in depancreatized dogs could be markedly reduced by the injection of amniotin. In view of the considerable amount of evidence supporting the view that the administration of oestrogenic substance suppressed the sex principle in the pituitary functioning, they thought that the postulated diabetic principle in this might also be capable of control on similar lines. They used amniotin as the vehicle of this oestrogenic substance since it was available in an oil solution, giving a slower and more uniform rate of absorption. It was found that the wounds in the experimental animals healed promptly under this treatment, and life was prolonged, although a gradual loss in weight occurred. A possible explanation submitted is that the pituitary function is suppressed in this way. If this is the case, there appears to be an obvious danger that other organs might atrophy. The authors therefore give the warning that, before attempting to treat clinical diabetes by pituitary suppression, it will be necessary to determine whether the influence on carbohydrate metabolism can be accomplished without serious injury to other organs. Investigations along these lines are proceeding.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

45 Primary Cardiac Rheumatism

A. HANNS and J. WORTER (*Arch. des Mal. du Cœur*, September, 1933, p. 545) put on record two new examples of primary cardiac rheumatism. They remark that although this condition is well recognized it is uncommon, and that most of the accounts hitherto given have related to endocarditis. Primary rheumatic pericarditis and primary rheumatic myocarditis, which are rarer, are exemplified in the two clinical accounts presented by the authors. The first patient was a man of 45 who had suffered from acute articular rheumatism fifteen years previously. He developed a pericarditis with effusion without any accompanying joint symptoms. On account of the poor general condition of the patient and the mode of onset of the illness, tuberculous pericarditis was diagnosed initially. A rapid regression of symptoms followed salicylate administration, but a week later acute articular rheumatism supervened. In view of these events the initial pericarditis was regarded as rheumatic in origin. The second patient was a man of 38, who presented the usual signs of congestive failure without previous illness or obvious cause. A slight fever appeared, this increased after one week, and at the same time acute inflammation of the right knee and ankle and other joints occurred. A diagnosis of primary rheumatic myocarditis with acute articular rheumatism was made. Administration of salicylates in large doses and the usual cardiac remedies brought about simultaneous improvement in the cardiac and articular conditions. The patient was discharged from hospital cured three weeks later.

46 Diet and Gall-Stones

E. J. HENNINGSEN (*Hospitalstudende*, September 21st, 1933, p. 60) produces statistical evidence in support of the view that variations in a nation's dietary from one period to another may be reflected in the death rate from gall-stones. In the period 1870-90 Denmark was comparatively spartan at table. Since then, with the exception of the lean years of the war, the national dietary has grown generous, particularly in meat and fats. The mortality returns for the Danish towns show that in the period 1890-9 there was an annual mortality from gall-stones of 2 per 100,000 living inhabitants. This figure rose to 4 in the period 1900-9. Between 1907 and 1913 it ranged from 4.5 to 6, reaching the imposing figure of 8.5 in 1913. It fell in 1914 to 6.5. In the period 1917-18 it ranged between 4 and 4.7. In 1919 it rose again to 7.3. From then onwards it continued to rise till it culminated in 1926 with 9.2. The gall-stone mortality in rural areas was, in 1920, lower than that in the towns; but it has shown the same tendency to rise, and in 1927 it drew level with the town mortality at 7.3 per 100,000.

47 Diagnostic Value of Superficial Eye Examination

C. BERENS and J. ZUCKERMAN (*New York State Journ. Med.*, September 15th, 1933, p. 1097) indicate the diagnostic points in cases of extracocular and systemic diseases which may be detected by examination of the vision, the position of the eye in the orbit, and the eyelids. Defective vision, for example, may be traceable to corneal opacities, lens changes, and diseases of the media which owe their inception to tuberculosis, syphilis, diabetes, hypertension, focal infection, or brain lesions. Exophthalmos may be caused by syphilis or tuberculosis of the orbital bones and periosteum, or by extension of infection from the nasal accessory sinuses, or by thrombophlebitis of the orbital veins following scarlet fever, or infection of these sinuses and of the tooth sockets. Influenza and rheumatism may give rise to inflammation of Tenon's capsule and exophthalmos. The commonest cause of bilateral

exophthalmos is Graves's disease, but high myopia, cranial anomalies, and bilateral orbital tumours may have this effect also, as well as sinus thrombosis. Enophthalmos occurs in the aged, extreme emaciation, paralysis of the sympathetic, congenital defects, and as the result of trauma. Scars along the outer upper margin of the orbit sometimes follow tuberculosis of the orbital bone; above the nasal angle of the eye they are usually the sequels of infection in the ethmoid cells. Bacterial allergy is indicated by recurrent attacks of slight redness and swelling, particularly of the upper eyelids, with slight scaling and itching. Non-inflammatory oedema of the eyelid may be of diagnostic significance in commencing heart failure, nephritis, and myxoedema. An early sign of Graves's and Addison's disease is marked pigmentation of the lower eyelid. Increased size of the palpebral fissure may be caused by a large myopic eyeball, abscess in the orbit, retrobulbar tumours, and arterio-venous aneurysms in the cavernous sinus.

48 Mechanism of Infection in Poliomyelitis

H. K. FAJER (*Amer. Jour. Pub. Health*, October, 1933, p. 1024) discusses some of the problems concerned with the conveyance of the virus of poliomyelitis and its mode of action in the body. In addition to personal and (rarely) milk transportation he is inclined to incriminate dust carried by air currents. He urges the need of further attention to this possibility, which would account for certain unexplained outbreaks. The site of implantation is, he thinks, the nasal mucosa, and not the lower respiratory or intestinal tracts. The author concludes that the olfactory bulb may well be the initial focus within the central nervous system of poliomyelitic infection, from this site the virus spreads directly along the nerve axons. Fajer argues that the clinical manifestations afford further evidence of such a route being followed. Failure of the virus to complete its journey to the anterior horn cells of the cord would explain the occurrence of cases of non-paralytic infection. He doubts whether the frequency of such cases is as high as some have thought (10 to 1 case of paralysis), and thinks that in epidemics an average frequency of non-paralytic cases is about 2 or 3 to 1. He is satisfied that the value of convalescent serum as a prophylactic is undoubted—at any rate for a few weeks—and urges its supply in epidemics to allay alarm and reduce the number of susceptible persons.

Surgery

49 Congenital Dislocation of the Patella

H. ROCHER (*Bordeaux Chir.*, October, 1933, p. 365) describes the operative technique he has adopted in a case of recurrent congenital dislocation of the patellae by transplanting a bone graft into the external condyle of the femur. The condition occurred in a girl of 14 where both patellae easily and frequently dislocated on flexion of the knee-joint and reduced themselves spontaneously on extension of the knee. The operation carried out consisted in opening the knee-joint and exposing the external condyle. A bone graft, which was taken from the tenth rib near the posterior angle, was then fixed near the outer border of the condyle of the femur. This graft lay against the outer edge of the patella and prevented its lateral displacement when the knee was flexed. The result of the operation appeared satisfactory, and so the second operation on the opposite knee was carried out, but without actually opening the knee-joint. In this instance the bone graft was attached to the condyle of the femur at the edge of the articular surface after pushing aside the synovial membrane. The patient, when

examined four years later, was able to walk normally and flex her knees completely without dislocating the patellae. The functional result was excellent, neither knee having been dislocated since the operation, in spite of the fact that the patient had had frequent falls. Radiograms showed the presence of bony shadows where the grafts had been fixed.

50

Aspiration in Cerebral Abscess

G. WORMS (*Ann. d'Oto-laryngol.*, September, 1933, p. 1029) advocates immediate and repeated aspiration of the small septic pockets which persist after evacuation of a cerebral abscess. This can readily be performed by using a simple glass pipette with abraded point, which can easily be introduced either directly into the cerebral tract, the operative wound being visible, or, when repeated with the patient in bed, into a rubber drain, sufficiently rigid not to close with the aspiration, one end being entered slightly into the abscess, the other projecting beyond the dressing. The pipette is connected to a rubber tube with a glass index at the vacuum source, a tube of water, or preferably to a surgical electric motor pump. Aspiration can thus be gently and completely performed without risk of cerebral traumatism, and permanent drainage is subsequently established. Cure is not always obtained, as sequels (epileptiform seizures) necessitating subsequent operation may persist. During aspiration the patient should be seated with the head turned to the sound side, which affords better separation of the edges of the pocket; deep respiration is also advisable, as this produces a maximum enlargement of the cavity to be drained. Notes of four cases, illustrative of the efficacy of this procedure, are appended; three of these were abscesses of the temporo-sphenoidal lobe of otic origin, and one a late abscess of the fronto-parietal lobe of traumatic origin. Two other cases, with advanced encephalitis when first seen, and in which death occurred after transient improvement, are also recorded.

51 Ramisection for Vascular Lesions of the Foot

J. KRIFPERT (*Zentralbl. f. Chir.*, September 30th, 1933, p. 2317) states that, although division of the grey rami communicantes in treatment of trophic lesions of the foot is an operation of considerable severity, it is justified by its striking success in trophic lesions which are due to functional conditions (such as angiospasm or Raynaud's disease) rather than anatomical—for example, endarteritis obliterans. He records two successful cases of ramisection for morbid neurovascular conditions of the foot of toxic origin. The first patient, a girl aged 11, had bilateral swelling, bony dystrophy, and redness about the tarsus; the second, a male aged 31, had cyanosis and partial necrosis of the great toe, with appearances in the adjacent toe resembling those of Raynaud's disease. In the second patient the grey rami from the third lumbar to the second sacral sympathetic ganglia were divided; in the first these were divided on one side, and at the same operation, retroperitoneally, the first and second sacral rami of the other side were cut. Disappearance of pain and redness and progressive restitution of function followed operation at once in each case, and operative resection of a gangrenous portion of the toe in the second case led to healing by first intention.

52

X-Ray Diagnosis of Gall-Stones

C. KREBS (*Hospitaltidende*, September 21st, 1933, p. 35) notes that there is still some disagreement as to the diagnostic value of the x rays in cholelithiasis. He has analysed the material in a Danish hospital for the period January 1st, 1927, to April 1st, 1933. Only those cases were considered in which the diagnosis of gall-stones was confirmed at an operation or a post-mortem examination. Among 100 such cases there were forty-eight in which an x-ray diagnosis of gall-stones could be made, and thirty-nine in which the x-ray evidence was suggestive of gall-stones without being conclusive. In twelve cases the x rays contributed nothing of value to the clinical diagnosis, and in one case the x-ray evidence was actually misleading. The conclusion drawn from these observations is that the absence of definite x-ray signs of gall-

stones does not justify the elimination of this diagnosis. On the other hand, in a considerable proportion of cases the x rays are, he states, of great value to the surgeon.

Therapeutics

53

"Work Therapy" in Diabetes

F. BRAUCH (*Zentralbl. f. innere Med.*, September 30th, 1933, p. 865) states that since the discovery of insulin the therapeutic possibilities of judicious and even occupational exercise in diabetes have been greatly increased. It was soon found that an insulin-sparing action of muscular exertion was demonstrated by cases in which the latter was repeatedly followed by hypoglycaemic crises in those receiving insulin, and this author mentions the case of a patient taking 20 units of insulin thrice daily who had hypoglycaemic attacks after taking up gardening, and who could avert these by increasing his intake of bread or omitting one or two of his daily injections. In an institution for diabetics Brauch found that most patients receiving insulin reacted to work by diminished glycaemia and/or diminished glycosuria; and, even in cases of some severity, he found that many patients previously unfit for work could be brought, by a suitable combination of dietetic and insulin therapy, to return to their occupation. He lays down the following principles to be followed in "work therapy" in diabetics. The worker must not forget, but must observe with special care, his dietetic rules. A high protein diet is preferable to one composed chiefly of vegetables and fats; and the calorie intake must be adapted to varying degrees of exertion. Insulin dosage must be altered when the severity of the labour alters—being increased, for example, in sensitive subjects on Sundays. The patient must carry sugar and be instructed regarding hypoglycaemic symptoms; in any case careful medical supervision is necessary during the first few weeks' return to work, and is best given in a suitable institution. It must be remembered that work may be followed by hyperglycaemia without glycosuria. Muscular subjects are better fitted for work than the obese or weakly diabetic, and work is contraindicated if cardiopathy is present. Excretion of the acetone bodies in considerable amounts contraindicates exertion, which is not necessarily harmful, however, if small amounts of acetone only are voided.

54

Carbon Tetrachloride as an Anthelmintic

J. A. CARMAN (*East African Med. Journ.*, September, 1933, p. 181) discusses the value of carbon tetrachloride in the treatment of hookworm disease and taeniasis. He points out that there is a heavy preponderance of evidence as regards its safety and efficiency in this respect, and, since the drug is now included in the *British Pharmacopoeia*, it can no longer be considered as an experimental remedy. Experience has shown that with careful selection of cases and preliminary dosage with magnesium sulphate symptoms of poisoning do not occur. In the fatal human cases on record the commonest factor present was alcoholism before or after treatment, but in a few cases the patients had been recently anaesthetized with consequent liver impairment. Carman is satisfied that the drug is an effective anthelmintic in uncinariasis and taeniasis. He condemns the exhibition of extract of male fern as being inefficient in dispensaries staffed by native dressers unless the patient has been very carefully prepared. In such circumstances it is likely to give rise to fatal poisoning occasionally. The author commends a one in four mixture of oil of chenopodium and carbon tetrachloride; with this in several hundred cases he has encountered no untoward symptoms. No food is given to the patients in the evening before treatment. In the morning they take 2 drachms of magnesium sulphate in 2 ounces of water; the anthelmintic mixture is then administered, followed by another dose of the salt. The maximum dose of the vermifuge mixture is 60 minims for a well-developed adult male, and smaller doses for women and children.

Dermatology

55

Observations on Soft Chancre

A. N. CHAPIRO and J. E. KANDEL (*Rév. Franç. de Derm. et de Vén.*, July-August, 1933, p. 387) record their observations on cases of soft chancre treated at the Minsk anti-venereal dispensary during the period 1924-9. Simple chancreoid occurred in 92.7 per cent. of the cases, and there were 2.6 per cent. mixed hard and soft chancres. No cases of extragenital transmission of chancreoid were seen. As regards the number of ulcers, a single chancre was found in 55.5 per cent., two in 18.2 per cent., three in 7.4 per cent., and more than three in 18.9 per cent. The favourite sites for chancreoid in man were the balanopreputial sulcus (26.4 per cent.), the inner surface of the prepuce (21.7 per cent.), and the sheath of the penis (18.2 per cent.). The following complications were noted: Phimosis (12.2 per cent.) and buboes (41.9 per cent., of which 38.7 per cent. were on the right, 48.4 per cent. on the left, and 12.9 per cent. on both sides). The appearance of the buboes accelerated the process of cicatrization of the chancre. Peshyassotzkaia's observation that the increased incidence of chancreoid was invariably accompanied by an increase of syphilis was confirmed by a sudden rise of syphilis in 1930. The writers' experience also confirmed the view expressed by S. T. Pavlov, who maintained that chancreoid delayed the appearance of the constitutional symptoms of syphilis.

56

Chronic Lichen Simplex

D. E. H. CLEVELAND (*Canadian Med. Assoc. Journ.*, October, 1933, p. 368) defines lichen simplex chronicus as a persistent dry thickening of one or more circumscribed areas of skin, with scaling, pigment formation, and intense itching which may precede the other symptoms. Often known as neuro-dermatitis, it is to be considered a distinct nosological entity—not to be confused with eczema, although often associated with this disease. Allergic, psychoneurological, and occupational factors play an important part in creating the background upon which the symptomatology is displayed. Treatment must be general as well as local, the predisposing aetiological causes being eliminated. The author finds the local application of x rays is the most frequently successful agency, but large doses at long intervals are not so effective as small and frequently repeated doses. Cleveland does not consider ultra-violet rays so promising. The prognosis is uncertain unless the constitutional disorder is rectified, but spontaneous recovery after a very protracted course not infrequently occurs.

57

Ringworm of the Feet and Toes

I. S. BARKSDALE (*Med. Journ. and Record*, October 18th, 1933, p. 279) discusses the treatment of the so-called ringworm of the feet and toes (athlete's foot). He considers crystal-violet application the method of choice, fuchsin in combination with the heavy metals having proved in his experience a disappointing germicide. Bismuth violet (0.4 per cent. in a 10 per cent. glycerin solution) gave satisfactory results, but only after repeated application and very diligent and conscientious treatment. It was found necessary to apply the medication every day for a week or ten days. Thymol and salicylic acid, applied on two consecutive nights beforehand, was found to be a useful adjuvant. Finally, what is described as the ideal dehydrating, kerolytic, and germicidal agent was elaborated: a combination of bismuth violet 1 gram, salicylic acid 2 grams, and ethyl alcohol to 100 c.cm. Two or three daily applications of this mixture arrested the infection, and recurrence was only noticed in cases when all after-care was neglected. The author states that this trichophyton infection is not associated with any impairment of the general health or nutrition, and advises early diagnosis to avoid spread of the disease. He describes the onset as characterized by slightly reddened, moist, and swollen skin between the toes and on the soles and sides of the feet. If treatment is not started,

small watery vesicles ensue in twelve to twenty-four hours, with intense itching. Larger lesions follow, with areas of raw discharging subcutaneous tissue usually emitting a foul odour. The clinical diagnosis is confirmed by laboratory detection of the trichophyton.

Obstetrics and Gynaecology

58

Results in Tubal Operations

A. MANDELSTAMM (*Zentralbl. f. Gynäk.*, September 8th, 1933, p. 2132) pleads for conservation in operations on the Fallopian tube. After post-operative implantation of the tube in the uterus, it is possible, he finds, to secure lasting permeability in about half of the cases. Although sterility usually persists in spite of this, eight cases have been recorded of pregnancy going to term, and five of uterine pregnancy ending in abortion. Mandelstamm here records another case of issue of a healthy child at term, the circumstances were favourable in that the tube was microscopically normal, with permeable external ostium, gonorrhoea was absent, and the adhesion in the intramural part of the tube was probably due to mild infection in antecedent abortions. Dealing with uterine pregnancy after operation for tubal gestation, Mandelstamm describes a case of delivery at term thirteen months after operation, in which the right ovary was sutured to the reconstructed distal end of a right tube stump which was 2.5 cm. long. The left tube had already been excised for a previous tubal pregnancy. At least thirteen cases of normal pregnancy have been recorded after bilateral tubal resection, combined in some cases with that of a connecting wedge of the uterus. On the other hand, some twenty cases of tubal gestation have been reported after partial tubal resection for ectopic pregnancy.

59

Thymophysin in Labour

OTTO WALLIS (*Journ. Obstet. and Gynecol. British Empire*, June, 1933, p. 633) is astonished by the adverse report on the value of thymophysin* issued by Roques and MacLeod. He maintains that its applicability is not in straightforward labour, but "in cases of primary and secondary inertia with a not too overfatigued uterus." He points out that the increase of the performance of the normal strongly working uterus obtained by means of an injection of thymophysin must be considerably less than the increase of the performance of the inert uterus brought about by equal doses of thyrophysin. This use of thymophysin is illustrated by a record of fifty cases in which successive small doses—0.4 c.cm., followed, if necessary, by often no more than 0.02 c.cm. at one-hour intervals—definitely shortened labour. He prefers thymophysin even in the second stage, as less, not more, likely than pituitrin to cause tetanic contractions of the uterus and affect the local circulation. He has never met with such adverse effects. The duration of labour is definitely shortened by its use: (1) in conjunction with castor oil for initiation of contractions (it lasted 11 hours 35 minutes and 5 hours 45 minutes in two cases reported), and (2) in a large majority of cases of primary or secondary inertia. He emphasizes the view that the value of such a preparation can only be estimated from its effect in such cases as call for a labour stimulant.

60

Induction of Labour

D. G. MORTON (*Amer. Journ. Obstet. and Gynecol.*, September, 1933, p. 323) tried out in 150 cases a method of inducing labour in order to assess its reliability in toxæmic or other urgent indications. The patients included twenty toxæmic cases and 122 normal cases near term. There was one failure in each group. The routine was as follows: at 4 a.m., castor oil 30 c.cm.; at 5, 6, and 7 a.m., quinine 0.3 gram; at 7.30 a.m., a hot

* This drug, a combination of thymus and posterior pituitary extract, is made by the Chemosan Union, Vienna, and is obtainable from Paines and Byrne, Perivale, London.

enema; at 8.30 a.m., artificial rupture of membranes. This was performed under antiseptic conditions (30 c.cm. of 4 per cent. aqueous mercurochrome in vagina) with a fine hook. Pituitrin, 1 c.cm., was then applied intranasally every hour till pains were established. The average number of applications in multiparae was 2.9, in primiparae 3.2. It was found specially important, in cases where the pains went off, to repeat the pituitrin. Once established, labour was conducted normally, with sedatives, etc., as required. The onset was usually with severe prolonged pains, never tetanic. Foetal heads showed marked moulding, and forceps were required in "a number of cases" owing to secondary uterine atony; but harmful effects on the babies were "notably absent." These induced labours were found to last approximately half as long as spontaneous cases. The main factor in their duration was found to be the degree of obliteration of the cervical canal at the time of artificial rupture of the membranes. There were no maternal deaths and no serious infections. Febrile puerperia appeared in 10.1 per cent. of cases—mostly only technical. One baby was stillborn; one died on the third day of *B. coli* infection; one on the forty-second day of prematurity. One foetal complication occurred—a prolapsed cord. This was successfully diagnosed and treated by high forceps extraction, but this method is not recommended in cases where the presenting part is not fixed. The twenty-one cases induced for toxæmia were all markedly successful.

61. Stimulation of Labour Pains

T. ANTOINE (*Zentralbl. f. Gynäk.*, November 25th, 1933, p. 2770) states that at the II. Universitäts-Frauenklinik in Vienna recourse is first had, in cases of uterine inertia, to quinine salts, which are now (in accordance with the experimental work of Schübel) given in much smaller doses than formerly—six powders, at half-hour intervals, of 0.05 gram each by the mouth. About 10 per cent. of cases fail to respond, and are given thymophysin—also in much smaller doses than were customary, beginning with 0.2 cm. This is successful in over 90 per cent. of cases; in some of the remainder labour is found to follow comparatively quickly after rupture of the membranes, which is held to be indicated where pains are good and a thick bag of membranes exhibits, but with little extra protrusion through the os during the pains. Morphine and belladonna are very useful in treatment of uterine inertia when the os is rigid; and rest rather than stimulation is called for in uterine fatigue.

Pathology

62. Experimental Work on Poliomyelitis

R. SOUTHEY and MARGOT MCKIE (*Med. Journ. of Australia*, September 23rd, 1933, p. 404) have endeavoured to ascertain the neutralizing effect on the poliomyelitis virus of normal and of convalescent serum. From thirty-two healthy adults in Melbourne, ranging from 19 to 46 years in age, a total of 13 litres of blood was collected, from which a little over 5 litres of serum were ultimately prepared. Neutralization tests were carried out by mixing the serum in varying quantities with a 5 per cent. suspension of pooled virulent cords, leaving the mixture at room temperature for fifteen to twenty minutes and in the ice chest overnight, and inoculating it the following day intracerebrally into monkeys. The strain of virus used in the preparation of the cords was one that had been isolated locally from a fatal case of poliomyelitis, and that gave rise on intracerebral inoculation to complete paralysis of the monkey on the eighth or ninth day at the latest. Only small numbers of animals were available for the neutralization experiments, and the results were irregular; it appeared, however, that about 0.6 c.cm. of the pooled normal serum was able to neutralize the dose of virus employed. Different batches of convalescent serum used for comparison likewise gave very irregular

results, but on the whole suggested that the quantity necessary for neutralization was about 0.3 c.cm. It would thus appear that pooled normal adult serum possesses definite neutralizing properties to the poliomyelitis virus, though not so potent as those of convalescent serum. In the second part of their paper the authors recount detailed experiments on the immunological relationship between Australian and American virus strains. The monkeys used were few in number, but the general conclusion was that the degree of protection afforded by inoculation with one strain against subsequent inoculation with another depended to a considerable extent on the virulence of the first strain. A virulent Australian strain appeared to afford a considerable degree of protection against a virulent American strain, while previous work of Burnet and Macnamara's had shown that a moderately virulent Australian strain did not protect against a virulent American strain. They conclude that, in future work of this type, the virulence of the virus must be taken into account before drawing deductions on the immunological difference between strains of varying origin.

63. Histology of Cutaneous Myomata

In an attempt to shed some light upon the causation of pain in cutaneous myomata, GRZYBOWSKI (*Ann. de Derm. et de Syph.*, September, 1933) has made an elaborate histological study. Pain is elicited in the lesions by the slightest mechanical irritation, and by cold. The present author showed that this pain was probably due to the presence of nerve fibres in the tumours and not, as has been supposed, to contraction of the muscle fibres. Numerous sections were prepared by the silver impregnation method of Ramon y Cajal, and these showed that nerve fibres were present in enormous numbers in the tumours. They were more numerous and larger than those found in similarly prepared sections of the skin of normal finger tips. The nerve fibres were irregularly arranged in bundles, each bundle being in close association with a capillary blood vessel. Isolated nerves were also found, either interwoven with the muscle fibres or running with them, and occasionally there were little plexiform arrangements.

64. Differentiation of Gram-positive and Gram-negative Bacteria

D. W. BRUNER (*Journ. Bacteriol.*, October, 1933, p. 261) grew a number of different bacteria in a synthetic medium containing 0.1 per cent. sodium carbonate, 0.2 per cent. acid potassium phosphate, 0.2 per cent. urea, and 2 per cent. agar in distilled water with a pH of 7.2 to 7.4. It was observed that when a 20 per cent. extract of pig's pancreas in glycerol was added to this medium, the Gram-positive bacteria grew, while the Gram-negative bacteria did not. The addition of the pancreatic extract to infusion agar gave rise to no inhibition of these organisms, suggesting that organic substances present in the nutrient agar medium absorbed or reacted with the active principle in the extract. Microscopical examination of cultures of bacteria in the synthetic medium plus 20 per cent. extract revealed the fact that Gram-negative bacteria underwent lysis, which was partial after twenty-four hours' and complete after forty-eight hours' incubation. The Gram-positive bacteria, on the other hand, showed no evidence of lysis. Separate examination of the various enzymes present in pancreatic extract was then made. Lipase, amylase, and, incidentally, pepsin, were found to be inactive. Trypsin, on the contrary, was found to have the same effect as the original extract. The inhibition of the Gram-negative bacteria appears to be due to a process of enzymic digestion resulting in lysis. It is suggested that the synthetic medium containing pancreatic extract may be used to separate off Gram-positive from Gram-negative bacteria. Attention must, however, be called to the fact that tryptic activity does not develop in pancreatic extracts till they have stood for two or three weeks at refrigerator temperature, so that freshly prepared extracts should not be employed for this purpose.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

65 Spontaneous Pneumothorax in the Healthy

T. H. LARSEN (*Norsk Mag. f. Lægervid.*, October, 1933, p. 1130) records seven cases of spontaneous pneumothorax in otherwise healthy persons whose ages ranged from 20 to 34. Three recovered in a short time and one took more than a year to be restored to health. In one case the pneumothorax was still present at the end of two years, and in another case a small local pneumothorax was still present at the apex after one and a quarter years. An effusion which was detected in only one case appeared after one year, and led to absorption of the gas. There was never any rise of temperature. In spite of repeated examinations the Pirquet test was always negative in this case. Two patients were brothers. In two cases aspiration of air was performed, but without any lasting result.

66 Essential Paroxysmal Hypertension

J. M. PLANTYDY (*Nederl. Tijdschr. v. Geneesk.*, October 21st, 1933, p. 4774) records a case of essential paroxysmal hypertension caused by an adrenal tumour (phaeochromocytoma) in a man aged 28. The symptoms consisted in increasingly frequent attacks of palpitation, during which the systolic blood pressure was 325 to 310 mm. Hg and the diastolic 200 to 150 mm. Hg. Impairment of renal function was shown by rise in Ambard's coefficient from 0.06 to 0.15. The clinical diagnosis of a right suprarenal tumour was confirmed by a skiagram; operation was performed, and a tumour weighing 149 grains was removed. Shortly after the operation Ambard's coefficient fell to 0.10, and six months later to 0.06, when the systolic blood pressure was 115 and the diastolic 80. This case is the fourth example on record of complete recovery after surgical removal of an adrenal tumour for essential paroxysmal hypertension, the three previous cases having been reported by Mayo (1927), Shipley and Pincoff (1929), and Porter and Porter (1930).

67 Whooping-Cough: A General Survey

F. HODER (*Med. Welt*, October 14th, 1933, p. 1451), who gives a useful review of present knowledge of whooping-cough, states that the organism most frequently associated with this disease is that first isolated by Bordet and Gengou. The discoverers used a medium glycerin-potato extract, agar, and blood, and considered the last constituent as essential for the growth of the organism, at least in the early stages. It has, however, been shown that the bacillus can be "acclimatized" to grow on blood-free media. Outside the body it is still viable in dried sputum after three days, but taken altogether shows little resistance in such conditions. Infection occurs by transmission in the coughed-up drops of fluid. After the first week of the catarrhal stage contagion becomes less likely, since the organism disappears from the sputum. In the first five years of life the mortality is high but gradually diminishes with increasing age; in the first year of life it is greater than that of scarlatina and diphtheria combined. According to Hoder, general agreement as to the exciting cause of whooping-cough has not yet been reached. The different views are: (1) that the Bordet-Gengou organism is the exciting cause, (2) that pertussis is due to a mixed infection and in certain cases is related to the infectious fevers, and (3) the filterable virus theory. The mass of bacteriological and serological evidence seems, however, to support the old Bordet theory. Vaccines of the *Bacillus pertussis* have given encouraging results in prophylaxis and treatment; anti-bacterial sera are not so promising, though the con-

valent serum has been very successful in the hands of some workers. The vast number of non-specific therapeutic agents have shown no particular virtues. Reviewing the results of many workers who used mixed autogenous vaccines, stock vaccines, and special ones prepared by a German manufacturing firm, Hoder finds that though dosage varied widely the vaccine treatment led in many cases to improvement in a relatively short time, while some success in prophylaxis was also obtained. Other workers report consistent failure with vaccines. The present author, whilst admitting the necessity for more investigation, considers that the balance of evidence is in favour of vaccine therapy.

68 Whooping-Cough in Old Age

A. J. HALL (*Chir. Journ.*, October, 1933, p. 397), who reviews the literature and records two illustrative cases in a man aged 72 and a woman aged 73, states that whooping-cough as a possible diagnosis should be borne in mind in every case of severe paroxysmal cough in an elderly person for which no obvious organic cause can be found. The popular idea that old people may with safety be brought into contact with cases of whooping-cough is incorrect, whether they have or have not had it in childhood. An elderly person with unrecognized whooping-cough may be a serious source of infection to children. The attack in old persons is usually very distressing, and although not often directly fatal, it may be so or accelerate death from other causes.

Surgery

69 Carcinoma of the Colon

F. LAHLY (*Amer. Journ. Surg.*, October, 1933, p. 64), emphasizing the importance of early diagnosis and treatment of carcinoma of the colon, presents a series of cases of which 56 per cent. had noticed symptoms for six months or less, while 85 per cent. had had abnormal symptoms for less than a year. As the lesion is easily recognized by means of x rays and fluoroscopy with bismuth enemata, and as surgical removal is in most cases quite safe, the early recognition of the disease renders the probability of a cure quite considerable. The largest number of cases occur in the rectum and recto-sigmoid. The age incidence is highest between 50 and 70 years, and the cases are almost equally divided between men and women. Symptoms vary according to the location of the disease. Cases of carcinoma of the proximal colon show severe secondary anaemia. Symptoms of carcinoma of the distal colon are those of obstruction in varying degree. Lesions of the rectum show few signs in the early stages, but the appearance of blood and the presence of haemorrhoids should lead to high digital and sigmoidoscopic examinations. There was constipation or diarrhoea in all but nine out of the author's 100 cases; nausea and vomiting occurred chiefly in cases with obstruction, and loss of weight was present in 65 per cent. of cases. According to the author the surgery of the colon and rectum has until recently been of a very severe type, but the Mikulicz procedure has greatly lessened the mortality. Illustrations are given showing the two-stage removal of the right colon, hepatic flexure, and part of the transverse colon, with anastomosis of the ileum to the transverse colon by this procedure. By this method of treatment the danger of peritonitis is largely eliminated, and it is possible to remove large segments of either side of the colon with comparative safety. Further illustrations show the Mikulicz plan of removal of the descending colon or splenic flexure and the two-stage plan of removal of cancer of the rectum.

70 Pancreatic Fistula after Operation for Gastric Ulcer

According to G. E. KONJETZNY (*Zentralbl. f. Chir.*, October 7th, 1933, p. 2375) injury to the pancreas or its ducts during gastric or duodenal operations usually leads to a lethal pancreatitis, rarely to a pancreatic fistula. A case is described of the latter, following partial resection of the stomach and posterior gastro-enterostomy for benign ulcer. The fistula led to the body of the pancreas, whose duct appeared to have been sectioned: it persisted after the scraping away of the deep-seated local granulations. Ten months after the first operation the distal end of the fistulous track, which had a lumen of 1 mm. diameter and a wall of granulation tissue 7 mm. thick, was successfully implanted in the jejunum close beyond the gastro-enterostomy. The relations with the omentum were treated conservatively, and a thin india-rubber catheter was passed through the fistula before its implantation.

71 Renal Carbuncle and Paranephritic Abscess

According to H. BOEMINGHAUS (*Zeit. f. Urol.*, October, 1933, p. 659) there are two non-ascending pyogenic infections of the kidney—multiple (miliary) abscesses and renal carbuncle. The latter is less common, but seventy-eight certain cases have been recorded. These two haematogenous infections are indistinguishable clinically: acute onset with high fever and rigors and negative (or only slightly pathological) urinary findings are the rule. In certain cases pyrexia and renal pain or tenderness are absent. Renal carbuncle is, he states, distinguishable in many cases from multiple kidney abscesses by the pyelographic findings of characteristically displaced and obstructed calyces; such were the findings in twelve of the fifteen cases in which pyelography was done. Cure of the carbuncle by discharge into the renal pelvis may occur, but a paranephritic abscess usually forms. When healing does not follow incision of a paranephritic abscess renal carbuncle may be suspected; but Boeminghaus thinks the routine freeing and inspection of the kidney during the original operation is too severe a proceeding to be justifiable. The recognition of renal carbuncle calls for enucleation or nephrectomy, and the decision cannot be made before operation. Preoperatively, in cases of paranephritic abscess (it is said) a careful examination of the urine and urinary function and of the renal pelvis—including cystoscopy, ureteral catheterization, and pyelography—will often serve to distinguish cases requiring simple incision from those in which a large collection of pus in the kidney will call for enucleation or nephrectomy.

72 Instability of the Knee-joint

A. KRIDA (*Journ. Bone and Joint Surg.*, October, 1933, p. 897) states that injuries to the crucial ligaments occur when the knee is subjected to gross dislocation or subluxation. Either or both ligaments may be the seat of rupture, injury to the anterior crucial ligament being the more common. Following such injury the knee-joint frequently becomes the seat of a chronic instability which may be general in character, or specific with regard to the particular ligament involved. The characteristic instability associated with injury to the anterior crucial ligament consists of the ability to displace the tibia forward on the femur in extension or slight flexion. Damage to the posterior ligament makes possible the sliding backward of the tibia on the femur in the flexed position. Operative treatment, as devised by Hey Groves, consists of the use of fascia lata to replace the injured ligament and the firm anchorage of the reconstructed ligament in bone tunnels drilled through the femur and the tibia. The operation is fully described, and the author gives the result of his experience in eleven cases of reconstruction of the anterior crucial ligament. The ligament was found to be completely ruptured in three cases with varying degrees of attenuation and relaxation in the remainder. Eight cases have been followed up,

and are classified as good results. The patients have stable, painless knees with substantially complete ranges of motion, except one in whose knee flexion is limited to 15 degrees beyond a right angle at the end of a year.

Therapeutics

73 Histamine in Rheumatic Affections

A. GOVAERTS (*Bruxelles-Médical*, October 29th, 1933, p. 1536), discussing the anti-rheumatic therapeutic use of histamine, states that its cutaneous vascular reaction is most important. Anomalies of cutaneous functioning (lowered cutaneous temperature, etc.) and circulatory stasis are, he points out, common in rheumatic affections. Histamine relieves these conditions by causing cutaneous hyperaemia with cellular transudation and increased circulation and local temperature, which favours absorption of the exudates and elimination of waste products. In treatment, Govaerts employs the ionization method of Deutsch, and uses compresses impregnated with 20 to 40 c.cm. of a 1 in 20,000 solution of histamine. These are connected to the positive pole of a continuous galvanic current, the intensity of which should be one-third of a milliamperé per square centimetre of surface to be treated. Deutsch also recommends applications over the articulations and muscles controlling these. Govaerts has employed this method in twenty-four cases of various rheumatic "algias" with complete relief in 62 per cent., marked alleviation in 16 per cent., and failure in 22 per cent. He considers that this technique, which does not preclude the use of other measures, is efficacious in relieving muscular pains in certain cases, such as contractures and conditions of non-inflammatory arthritis and peri-arthritis.

74 Magnesium Sulphate in Status Epilepticus

F. STORCHEIM (*Journ. Amer. Med. Assoc.*, October 21st, 1933, p. 1313) found that genuine status epilepticus did not respond to morphine, with atropine, chloral, and ether or chloroform anaesthesia. Intravenous injections of magnesium sulphate, however, prevented death, and reduced the number of subsequent attacks. He states that an injection of 10 c.cm. of a 25 per cent. solution of the salt is, apparently, a safe dose, and as a rule brings the attack to a speedy termination. If necessary it may be repeated, and possibly even be given a third time in a well-developed patient; but this is the limit of safety. Storchheim comments on the parallelism that has developed in the treatment of eclampsia and status epilepticus, with the discarding of morphine and narcotics in favour of magnesium sulphate. He suggests that the underlying pathological changes in the central nervous system are analogous, if not identical, in the two conditions. He adds that the beneficial influence of the salt on the oedema of the lungs, as well as on the brain, may play an important—or even the deciding—part. The maximum dose of magnesium sulphate which can be regarded as safe is given as 7 or 8 grams.

75 Treatment of Lobar Pneumonia

F. BARDACHZI and W. SEKELES (*Med. Klinik*, October 6th, 1933, p. 1374) emphasize the importance of bodily and mental rest in the treatment of pneumonia, and state that if these cannot be secured in the patient's home he should be carefully transported to a hospital, where all unnecessary examinations and demonstrations must be forbidden. Pain, restlessness, and irritating cough call for morphine, in not too small doses, and preferably combined with atropine, while for sleeplessness it should be given in the minimum effective amount. If circulatory failure seems likely, large doses of digitalis are to be given; if it is present, strophanthin, or in less severe cases camphor, is called for. Venesection is very useful for relief of the lesser circulation. In specific treatment the writers prefer, to serotherapy, injections of the basic

salt of ethyl-hydrocuprein (optochin). In their hands this drug seems to have halved the pneumonia mortality during the last five years, and they have not found toxic visual disturbances to follow its use if an alkaline milk diet is prescribed. Like Cross, they give the optochin in four-hourly doses of 0.2 gram for three days.

76 Oestrin Therapy in Haemophilia

R. L. BROWN and F. ALFRIKH (*New England Journ. Med.*, September 28th, 1933, p. 630), who have tested the value of progonyn and theelin administration in a case of haemophilia, found no definite changes were observed in the clotting time or in the number of platelets, although urinary examinations revealed that the patient was excreting the hormone in amounts far exceeding those present in normal women. Before this line of treatment started the patient was excreting considerable amounts of substance (possibly the male sex hormone) which produced oestrus in castrated female rats. Since there can be no doubt that in this case the dosage was fully adequate, the authors conclude that little benefit is to be expected in haemophilia from oestrin injections.

Ophthalmology

77 Ocular Tuberculosis

J. L. PAVIA (*Rev. Sud-Amér. de Méd. et de Chir.*, September, 1933, p. 641) believes that, except in the rare cases of traumatism, this condition is secondary, and that a primary focus always exists. Infection probably occurs through the blood (chiefly the veins), though convection by the lymphatic cannot be excluded. Repeated re-infections cause a certain degree of immunity in cases of ocular tuberculosis; a state of hypersensitivity is also produced, with repeated local haemorrhages and formation of uveal tubercles, first in the ciliary body, then in the iris, and finally in the choroid. The prognosis is grave, as the sclerotic undergoes purulent effusion necessitating enucleation of the eye. Many forms are noted between phlyctenular conjunctivitis and the scleritis produced by lymphatic formations on the bulbar conjunctiva and sclerotic. Phlyctenular forms should immediately receive tuberculin, as recurrences endanger vision. Involvement of the episclera and sclerotic may also arise. Disease of the deep sclerotic layers favours inflammatory extension to other membranes, and troubles of vision occur. There may be uveal involvement and tubercle formation in the great anterior circle and base of the iris, the ciliary body, and equatorial choroid region. Tuberculous retinitis is important only owing to its mechanical effects, while disease of the optic nerve, due to infection from the retina or pia mater, is occasionally found. For diagnosis, Pavia practises the intradermal reaction, injecting 0.5 c.cm. of a 1 in 400 solution of tuberculin T.R. into the skin. Therapeutic measures are: climatic treatment, tuberculin therapy combined with radiotherapy, and sub-conjunctival injections of sodium chloride, either alone or with 1 to 4 per cent. of iodoform. Comment is made of the diagnostic method, in certain cases, of Meller, who makes cultures by the Loewenstein technique from an eye needing enucleation.

78 Acute Inflammation of the Orbit in Children

R. C. GAMBLE (*Arch. Ophthalmol.*, October, 1933, p. 483) points out that the difference in the course of this disease in adults and children is due to the smaller size but more active growth of the sinuses, the greater tendency to septicaemia after abscess incision, the greater ease with which pus travels along fascial planes, and, finally, the greater resistance of the cornea in children. Orbital cellulitis may arise from direct wounds, from adjoining infection, or from embolism. The majority of cases are due to ethmoiditis and antritis. Swelling of the lid with increased nasal discharge on the same side is usually the first sign. Resolution may follow hot or cold applications, the use of ephedrine, and a mild silver protein in

the middle meatus combined with nasal suction. In severe cases proptosis appears, while fixation of the globe or chemosis indicates pus formation. Though a subcutaneous swelling above or below the tendo oculi demands incision, radical intranasal operations or orbital incisions should usually be avoided because metastases so often follow. Acute orbital priestitis and osteomyelitis may occur as a metastatic infection without concurrent sinusitis. Osteomyelitis of the maxilla, due to trauma plus infection, is more common in infants than in older children.

79 Psychoneuroses of Ophthalmic Origin

C. K. GUOSU (*Calcutta Med. Journ.*, September, 1933, p. 111) comments on the number of cases in which symptoms of neurosis are definitely related to the eye. Local treatment fails to remedy the condition, and may even make it worse, owing to the patient's attention being thus concentrated upon the eyes. The author cites various instances of these neurotic ophthalmic symptoms, which include asthenopia, lid tremors, amaurosis, amblyopia, photophobia, and ocular hyperaesthesia. The most common field defects are said to be general depression and concentric contraction, which is often star-shaped, reversal of the colour fields, or interlacing of their boundaries. Such field changes present inconsistencies *per se* very often, and indicate the existence of a deeper cause of a non-organic nature. The author advises that such possibilities should not be overlooked, since long treatment with no resulting benefit may aggravate the underlying neurosis and postpone the urgently needed psychotherapy.

Obstetrics and Gynaecology

80 Chloride Metabolism and Hyperemesis Gravidarum

H. KRETZSCHMAR (*Zentralbl. f. Gynäk.*, October 7th, 1933, p. 2353) draws attention to the resemblance between the clinical pictures of (1) an advanced stage of pernicious vomiting of pregnancy, and (2) hypochloroemia. In the latter, diminution of the blood and urinary chlorides is associated with weakness, wasting, persistent vomiting, diarrhoea, and mental apathy; and a lethal uraemic coma may ensue, the kidneys showing no characteristic necropsy changes. He suggests that the toxic symptoms of advanced cases of pregnancy hyperemesis may be due in part to the hypochloroemia following repeated vomiting of hydrochloric acid from the stomach: according to this view the vomiting, probably at first of psychogenic origin, leads to hypochloroemia, which sets up further vomiting, and induces a vicious circle. Kretzschmar describes a case of pregnancy hyperemesis with rapid wasting and toxic symptoms including jaundice, pyrexia, and apathy alternating with excitement; the chloride content of the blood was markedly diminished. Treatment by insulin injections and rectal injection of glucose was ineffectual. The vomiting gradually ceased, however, and the weight increased, *pari passu* with the return of the blood chlorides to normal as a result of rectal and intravenous injections of sodium chloride. This treatment, it is said, well deserves trial in cases of hyperemesis gravidarum which have not responded to psychotherapeutic and the other usual treatments: in the case recorded it saved the induction of abortion, which had appeared inevitable. R. KESSLER and H. ALBERS (*ibid.*, October 21st, 1933, p. 2479) record two cases of hyperemesis gravidarum in which the blood chlorides were diminished and the non-protein nitrogen of the blood greatly increased: in both cases a pyelitis had preceded the vomiting, and a salt-free or salt-poor diet had been given. They point out the clinical and biochemical similarity between pernicious vomiting and the condition of dehydration, hypochloroemia, and azotaemia which occurs, from loss of chlorides, in the persistent vomiting of intestinal stenosis. In both conditions there is no primary renal affection to explain the retention of urea and other non-protein nitrogenous substances. Allusion is made to the possible noxious

effects of a salt-poor diet in pregnancy, and to the therapeutic possibilities of oral or intravenous injection of sodium chloride, which in the cases described led to diminution of the blood nitrogen and increase of the chlorides. It is suggested that in treatment of hyperemesis the hypochloroemia should receive attention as well as the acidosis.

81 Sharp Curette in Treatment of Abortion

A. A. PUNTEL (*Semana Médica*, September 28th, 1933, p. 879), in the course of a lengthy paper, strenuously advocates the employment of the cutting curette for the removal of all remnants of the embryo which persist after quinine, ergotamine, pituitrin, and vaginal tamponage have been tried. Abortion complicated by the coexistence of salpingitis, parametritis, and pelvic peritonitis he places on another plane, and in such cases abstains from all intrauterine manoeuvres. Stating that there are two schools of thought—namely, the "abstentionists" and the "interventionists"—and having quoted the work of almost fifty writers, of whom only two are British, Puntel ranges himself enthusiastically on the side of the latter school. Full histories are given of sixty-one of his own cases of abortion, of which but one proved fatal; this last was septicæmic on admission to hospital, and the curette was therefore not employed. The author does not mention the value of glycerin in septic metritis.

82 Premature Rupture of Membranes

L. W. MASON (*Amer. Journ. Obstet. and Gynecol.*, September, 1933, p. 395) analyses the effects of spontaneous rupture of membranes at or before the onset of labour pains in 166 cases occurring in a series of 1,000 normal deliveries. Comparing the premature rupture cases with those occurring after dilatation of the os, he reports in the former a definite and marked tendency to shorter labours, with no demonstrable effect upon foetal or maternal mortality or morbidity. He questions the value of the hydrostatic wedge, and suggests that dilatation of the cervix is primarily a process intrinsic in the uterus and cervix.

83 Ovarian Hormones in Amenorrhoea

C. KAUFMANN (*Klin. Woch.*, October 7th, 1933, p. 1557), whose previously published work indicated that the whole menstrual cycle could be re-established in a castrated woman with atrophied uterine mucosa by the administration of folliculin and the corpus luteum hormone, states that this required much larger amounts than those commonly used, 200,000 mouse units of progynon being the minimum dose for a single injection. He believes that many failures are due to underdosage. The mere appearance of bleeding is not a sufficient criterion of success, for not all bleeding after the administration of ovarian hormones is due to menstruation. Intermenstrual haemorrhage can be produced in the monkey by injections of folliculin alone, whilst true menstrual bleeding can only be obtained by folliculin and corpus luteum combined. Great overdosage with folliculin can, even in the castrated subject, lead to abnormally great proliferation of the uterine mucosa—the so-called glandular cystic hyperplasia. The author quotes a case of a castrate woman of 28 years to whom 1,100,000 mouse units of folliculin were administered, and in whom a brownish uterine discharge was induced, curettage demonstrating the typical cystic hyperplasia. In such hyperplastic uterine mucosa glycogen is not found; but if, in addition, corpus luteum is injected glycogen appears in this situation. The author's technique in the treatment of amenorrhoea is to inject 1 c.cm. of highly active progynon (1 c.cm. = 50,000 mouse units) twice a week for three weeks. After this time 25 to 50 rabbit units of a corpus luteum preparation (proluton) is injected over a period of five days. In five cases of primary amenorrhoea with hypoplastic or infantile genitalia, the author found a demonstrable increase in the size of the uterus after treatment with very large doses of progynon in two cases only. This increase in size may be accompanied by short periods of haemorrhage, which the author calls

"follicular haemorrhages." In two cases of primary amenorrhoea with well-developed genitalia Kaufmann used both follicle and corpus luteum hormones with successful re-establishment of menstruation. In secondary amenorrhoea (eleven cases) good results are claimed with large doses of progynon alone.

Pathology

84 Bacteriology of Acute Peritonitis

P. CAZZAMALI and R. MGLIERINA (*Arch. Ital. di Chir.*, September, 1933, p. 573) record the results of examination of eighty-one cases of acute peritonitis. The majority of these (sixty-four) followed appendicitis, ten followed perforation of a gastric or duodenal ulcer, while the remainder were of miscellaneous origin. The general technique consisted in the withdrawal of peritoneal exudate by sterile pipettes from different parts of the sac as soon as the abdomen had been opened, microscopic examination of films of the exudate, and cultures under aerobic conditions on blood and ascitic fluid agar, and under anaerobic conditions on these media and in Tarozzi's and glucose liver broth. In nine instances the exudate proved sterile. From ten exudates only one species of micro-organism was cultivated; from twelve exudates, two; from seventeen, three; from nineteen, four; from seven, five; and from two six different species were cultivated. Aerobic organisms accounted for about two-thirds and anaerobic organisms for about one-third of the total isolated. In the sixty-four cases of appendicitis the commonest organisms were as follows: *B. coli* 84 per cent.; streptococci (generally haemolytic or non-haemolytic, seldom of the *viridans* type) 73 per cent.; Gram-positive non-sporing anaerobic diptheroids 30 per cent.; *Cl. welchii* 25 per cent.; and the anaerobic organism sometimes known as *Fusiformis fragilis* 22 per cent. *B. coli* and streptococci were associated in 67 per cent., and *B. coli*, streptococci, and *Cl. welchii* in 25 per cent. In the nine fatal cases of appendicitis *B. coli* and streptococci were both present. Generally speaking, it was found that the more limited the inflammatory area and the shorter the time it had existed, the fewer were the total bacteria present, and the less numerous were the numbers of different species. In point of time the aerobic appeared to precede the anaerobic organisms. *B. coli* seemed to be able to diffuse more rapidly through the peritoneal cavity than any other organism, while streptococci were able to persist for the longest time. As regards prognosis they were unable to confirm the statement that active phagocytosis was necessarily of good omen. The fewer organisms and the fewer different species there were present, the more favourable was the outlook. When organisms were seen in film preparations but little or no growth occurred in culture, the case was likely to be benign. When, on the other hand, more species appeared in culture than were seen microscopically, the case was likely to be serious. It was noteworthy that in perforated gastric or duodenal ulcer cases the peritoneal cavity generally remained sterile for six hours, and sometimes even for twelve hours, but after this time it was always infected. The commonest organism in this type of case was the streptococcus.

85 Blood in Osteo-articular Tuberculosis

M. M. ALTSCHULER and N. W. STRIER (*Zeit. f. Tuberk.*, October, 1933, p. 417) examined the blood of 180 children with osteo-articular tuberculosis aged from 2 to 16 years (by Van Slyke's method) with the following results. (1) In closed forms of the disease the alkali reserve of the blood became increased. (2) In open forms—that is, in mixed infection—the alkali reserve was diminished. (3) There was a certain parallelism between the severity of the disease and the amount of alkali reserve in the blood. (4) In 60 per cent. of the cases there was a parallelism between the amount of alkali reserve in the blood and the leucocyte picture.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

86

Acute Lead Poisoning

A. SCHREITZENMAYR (*Deut. med. Woch.* October 20th, 1933, p. 1601) describes an instructive case of this condition. The young patient was in the fifth month of pregnancy, and although the sequence of symptoms of which she suddenly began to complain were those typical of lead poisoning, this was not diagnosed for a considerable time. The patient at first denied the taking of an abortifacient, but later admitted it. The usual therapeutic measures were of no avail. The spastic ileus was treated with high nutrients, enemata, and intravenous belladonna preparations, and magnesium sulphate and belladonna by mouth were tried without success; the colic was temporarily relieved by the belladonna, but soon returned; iron and liver were used to combat the severe anaemia, but the haemoglobin continued to fall until the figure of 29.4 per cent. was reached. Muscle weakness became more and more marked, the pulse was small and rapid, and blood pressure was low. It was thereupon decided to convert this acute lead poisoning into a chronic form. Large doses of milk and daily intravenous injection of 10 c.cm. of 10 per cent. calcium gluconate were followed by phenomenal success, the symptoms rapidly abating and the haemoglobin percentage showing a quick rise. This treatment was continued for forty-two days, when the haemoglobin had reached 50 per cent. and the red blood cell count was 3,168,000. Stoppage of the treatment for five days brought about a fall in haemoglobin. The patient left hospital a typical case of chronic lead poisoning. Intolerance to calcium now set in, and the administration was stopped. The excretion of the lead now began. Pregnancy proceeded to a normal termination, and a rather weakly child was born, which, however, progressed well on the bottle. The author quotes this case as being an unequivocal demonstration of the value of forcing the circulating lead into the bone depots and then allowing of its slow excretion after the acute manifestations have been controlled.

87

Sinusitis in Scarlet Fever

G. D. HOORLE and L. S. CAVE (*Journ. Amer. Med. Assoc.*, October 7th, 1933, p. 1121) have made a study of two series of cases of scarlet fever. The first consisted of 292 patients, examined chiefly by x rays, while in the second group, consisting of eighty patients, an attempt was made to correlate the clinical and x-ray findings. In both series x-ray evidence of sinusitis was present in approximately 90 per cent. of the cases. Clinical examination, however, failed to confirm the evidence in every case. There were thirty-three cases of otitis media in the first group of 292 patients, and twelve in the second group of eighty patients. In all these there was x-ray evidence of sinusitis, and in all but one the sinusitis was on the side of the infected ear.

88

Gastritis

The recent reorientation of opinion on the question of gastritis is due, according to J. DOBERER (*Med. Welt*, October 21st, 1933, p. 1493), to the histological examination of resected stomachs, to the introduction by Berg of the relief method of radiography in the examination of the stomach, and to the development of gastroscopy. In past years it is probable that a number of different pathological conditions were referred to loosely as gastritis. Doberer describes one of these conditions, which he has named gastritis adhaesiva. Gastritis adhaesiva is accompanied by all the symptoms of peptic ulcer. On the abdomen being opened at operation, there is a diffuse injection of the serosa of the pyloric antrum and peri-

gastric and periduodenal adhesions. Resected specimens show an inflammation of all coats of the juxta-pyloric portions of the stomach and duodenum, and frequently ecchymosis or erosion of the mucosa; similar findings are present in peptic ulcer, and Doberer considers that gastritis adhaesiva is a pre-ulcerous state. The same aetiological factors are present in gastritis adhaesiva as in peptic ulcer, and the differential diagnosis depends upon the radiographic findings. Treatment is ambulatory, and consists of a bland diet, alkalis, and belladonna. Doberer recommends that general treatment to combat the "ulcer diathesis" should also be employed, and suggests injections of arsenic. Should the abdomen be opened and gastritis adhaesiva without ulceration be found, the author considers that a prophylactic partial gastrectomy should be performed.

89

Pellagra

A. HORMAN-BANG (*Hospitalstidende*, November 2nd, 1933, p. 1089) gives an account of seven cases of pellagra observed in a Danish asylum. He was aided in his recognition of the true state of affairs by the investigations of Hess-Thaysen, who has recently shown that pellagra is by no means a rare sequel to a "sloppy" diet, and that chronic diarrhoea, by interfering with the adequate absorption of the vitamin in question, favours what is now known as secondary pellagra. Hess-Thaysen suggested that a careful comb-out of lunatic asylums would not fail to yield a crop of such cases of secondary pellagra. In all the author's seven cases skin changes characteristic of pellagra were found, and in five cases the patients suffered from stomatitis as well as diarrhoea. The administration of a proprietary vitamin preparation was followed by the disappearance of the cutaneous lesions in two cases. Specific vitamin medication was not, however, strikingly successful as far as the mental condition was concerned, and in no case could it be put in a causal relationship with the pellagra. The chief lesson of this paper is that secondary pellagra may occur in Europe provided the dietary and the condition of the gastro-intestinal tract are favourable to it.

Surgery

90

Drainage in Diffuse Peritonitis

A. J. TRINCA (*Med. Journ. of Australia*, October 7th, 1933, p. 465) attacks the abuse of the drainage tube in the treatment of peritonitis, and records a series of 244 cases in which this procedure was not employed. He maintains that, owing to the nature and distribution of the contents of the peritoneal cavity, it is impossible to effect adequate drainage in cases of diffuse peritonitis, and that no attempt at it is necessary when the primary septic focus has been eliminated. He enumerates the possible harmful effects of using a tube, such as: aggravation of the existing peritonitis; faecal fistula; damage to omentum; injury to the abdominal wall; post-operative hernia; production of adhesions and consequent intestinal obstruction; introduction from the air of organisms, such as *B. pyocyaneus*; induction of ileus; and the delayed convalescence which follows some or all of these complications. In his opinion the rational treatment of peritonitis comprises the lightest possible anaesthesia, the greatest delicacy in operating, the removal of exudate only when mixed with gangrenous debris, visceral contents, or infective material, and the clearing out of omentum which is apparently infected or likely to become gangrenous. He concludes from an analysis of his series of cases that peritonitis in the early stages

is not a serious condition if dealt with on rational lines—namely, rejection of the drainage tube, and no inclusion of purgatives, involuntary muscle stimulants, and other lines of action which tend to accentuate inflammation in the after-treatment. Ileus was not found to be common, and Trinca attributes this sequel to bad surgery or unscientific post-operative care. The incidence of wound infection was high, but many of the cases were mild.

91 Peritoneal Syndrome in Acute Rheumatism

M. STOIANOVITCH (*Bull. et Mém. Soc. Nat. de Chir.*, October 28th, 1933, p. 1225) reports two cases of acute articular rheumatism which occurred in children. In each case the onset was accompanied by severe abdominal symptoms, and diagnosis of acute appendicitis was made. In the first case the child, a girl of 9 years, was admitted to hospital with acute generalized abdominal pain and raised temperature. The following day the abdominal symptoms subsided and pain developed in the left hip, knee, and ankle. The second case occurred in a boy of 7 and was similar in onset, with violent pain in the epigastrium and the right iliac fossa. Acute appendicitis was diagnosed, but the parents refused operation and took the child away. They returned the following day as the child had had an unusually violent attack. As there was now pain and swelling in the knee and ankle and a systolic murmur, with a lessening of the abdominal symptoms, operation was not recommended and treatment with salicylates was given. In both cases the joint and heart signs appeared at the end of four days, and coincided with the subsiding of the abdominal symptoms.

92 Back Pain and Sacralization of L5

According to R. INGEBRIGSTEN (*Zentralbl. f. Chir.*, October 7th, 1933, p. 2368), hypertrophy of the transverse process of the fifth lumbar vertebra is notable radiologically in 70 per cent. of cases, and its clinical significance as a cause of pain in the back has been much exaggerated. A one-sided bony union of the transverse process with the sacrum (sacralization) may, however, cause severe pain in the lumbar and sacral regions and very considerable limitation of spinal movement and walking. The writer describes his third case, in which resection of the ankylosed fifth lumbar transverse process has been followed by lasting cure of pain and crippling.

Therapeutics

93 Sarsaparilla in Chronic Nephritis

F. HUMPERT (*Klin. Woch.*, October 28th, 1933, p. 1696) confirms previous reports of favourable results in chronic nephritis, following the administration of "renotrat," a new preparation of sarsaparilla root. In several cases of chronic nephritis the blood nitrogen content was reduced in quantity, and headache, nausea, and anorexia were relieved. Five patients were treated while taking an ordinary purine-containing diet. Four were men whose ages ranged from 20 to 54 years, and one was a woman, aged 56. All had hypertension with albuminuria, casts, and erythrocytes in their urine. Three patients had albuminuric retinitis. Each patient was kept under observation for periods of from four to twelve days before treatment was commenced, and the total daily excretion of uric acid was estimated, as well as the uric acid blood content. During the ensuing twelve days one tablet of renotrat was given thrice daily. The total daily uric acid excretion was estimated by Benedict and Franke's method and the blood uric acid content by Morris's colorimetric method. After the drug had been discontinued each patient was observed, and the daily estimations of uric acid were continued for a further period of from four to twelve days. It is claimed that the favourable therapeutic action was definite in every case. The average daily excretion of uric acid was increased greatly, and

this persisted during the whole observation period. During the administration of renotrat the uric acid blood content was much reduced, but it usually increased slightly after cessation of the drug. In one case large doses of renotrat appeared to prevent the onset of uraemic coma. This drug is a powerful diuretic and induces a correspondingly increased elimination of uric acid.

94 Endocrine Treatment of Aspermia

W. L. BROSIUS and R. L. SCHAEFFER (*Journ. Amer. Med. Assoc.*, October 14th, 1933, p. 1227) report a case of spermatogenesis following the exhibition of a preparation of anterior-pituitary-like principle from pregnancy urine. A man, aged 33, had complete aspermia, following an attack of mumps at the age of 27, with a complicating bilateral orchitis resulting in bilateral testicular atrophy. Twice a week 2 c.cm. of the preparation (1.7 rat units per kilo of body weight) were injected into the gluteal muscle. Within two weeks there was a definite increase in the size and firmness of both testes, and a week later a few non-motile spermatozoa were found. At six weeks there were numerous non-motile spermatozoa, and at nine weeks large numbers of actively motile spermatozoa were present. The testes continued to increase, and there was a marked subjective improvement, symptoms such as lethargy, tremors, dizziness, and speech difficulties disappearing. The treatment was discontinued, but four weeks later the spermatozoa became few and non-motile, and the symptoms returned with softening and diminution in size of the testes. With the resumption of the injections all the favourable signs were again noticeable, and it was found to be possible to maintain the general health and active spermatogenesis on fortnightly doses of 2 c.cm. The authors argue that there appears to be evidence that the gonad-stimulating extract from pregnancy urine induces spermatogenesis, and that in this case the pituitary gland did not hypertrophy as in castrates with production of an excess of sex hormone.

95 Gold Tribromide in Whooping-cough

J. EFSTEIN (*Journ. of Pediat.*, October, 1933, p. 635) reports his observations on seventy-five cases of whooping-cough which he has treated during the last four years by gold tribromide. Ages ranged from 2 weeks to 8 years; two cases were adults. Treatment consisted in the oral administration of a solution of gold tribromide in water in doses (varying with the age of the child and the severity of the cough) from 1/20 to 1/10 grain three times a day after meals and one at midnight. The results were as follows: In about two-thirds of the cases the cough subsided in three weeks, and in the other in from five to seven weeks. In all cases after three or four days' treatment the cough was less frequent and distressing, and milder, the vomiting ceased, and sleep became more restful. There were no recurrences, complications, or deaths. In twenty-five controls who were given the ordinary remedies for pertussis the cough was frequent and racking, and the duration of the disease ranged from three to four months. The earlier the treatment was begun the quicker and better were the results.

96 Drinker Apparatus in Post-diphtheritic Respiratory Paralysis

J. E. GORDON, D. C. YOUNG, and F. H. TOR (*Journ. of Pediat.*, October, 1933, p. 580), who record two illustrative cases, maintain that the Drinker apparatus, which has been used with success in poliomyelitis for long-continued artificial respiration, forms a valuable addition to present methods of management in post-diphtheritic respiratory paralysis. Of the two cases reported, one, a girl aged 8; recovered, and the other, a youth aged 18, died. The writers believe that if artificial respiration by this method is started at the first sign of respiratory difficulty, a greater proportion of recoveries would be noted among patients with diphtheritic paralysis than with any other of the conditions that may be treated by this method.

Laryngology and Otology

97 Calot's Solution in Chronic Otorrhoea

J. C. SEAL (*Med. Journ. and Record*, October 4th, 1933, p. 244) has obtained excellent results in chronic otorrhoea by instilling into the ear Calot's solution (a mixture of guaiacol, creosote, ether, and iodoform in olive oil). After eradicating any contributory cause, such as diseased tonsils and adenoids, nasal polypi, and sinusitis cholesteatoma, as well as aural polypi and protruberant granulation tissue, the author dries the ear thoroughly and instils five drops of Calot's solution into the meatus. The head is held in a horizontal position, and tragus massage is employed, so that by pushing the tragus against the canal wall, and suddenly releasing it, the alternating pressure permits the solution to enter the Eustachian tube. This procedure is employed once a day for seven days, during which time the discharge will be found to become thin and scanty, and to disappear finally. After the last treatment, boric acid powder is insufflated. The author's percentage of success is 85. He states that in cases of failure tuberculosis of the middle-ear should be suspected, or diabetes, syphilis, or cholesteatoma. The efficacy of the mixture is attributed to the guaiacol and creosote, which act as a caustic on the granulation tissue. The ether dissolves and removes the debris and secretion covering the diseased area, permitting the caustic agents to reach the infected parts.

98 The Mastoid Vein in Infected Lateral Sinus Thrombosis

According to E. F. ZIEGELMAN (*Arch. of Otolaryngol.*, September, 1933, p. 298) the external mastoid (emissary) vein, although absent in a fairly large number of persons, may account for some of the high mortality in infected sinus thrombosis. The author records the anatomical results obtained from a series of dissections. He found that this vein was often linked with the general systemic circulation through some route other than that of the internal jugular vein or one of its tributaries. There is a very complex occipital venous plexus, and the mastoid vein may be connected with this in one of various ways. It may be invaded in an infected lateral sinus thrombosis, either by continuity of tissue initiating a phlebitis or by direct extension of a thrombus. The author concludes, therefore, that it should be carefully considered from a surgical point of view in all cases of infected lateral sinus thrombosis.

99 Progressive Nasal Ulceration

J. P. STEWART (*Journ. Laryngol. and Otol.*, October, 1933, p. 657), recording ten cases, describes a disease characterized by progressive destruction of the nose, face, and pharynx, which he terms "progressive lethal granulomatous ulceration of the nose." Nine of his ten patients were male, and eight cases occurred between the ages of 28 and 42. The duration of the disease is from one to two years, and a marked feature is the complete absence of any sign of resistance to it by the patient. There is a mild leucocytosis (about 15,000 cells per c.mm.), or a leucopenia of about 2,200, with no change in the differential count. From the clinical and microscopical appearances Stewart concludes that the destructive process cannot be classed as a tumour, but is essentially a chronic inflammatory and pyogenic condition. He can trace no association between it and Hodgkin's lymphogranuloma. The disease is not one of formation, but rather of destruction; the presence of granulation tissue is held to justify the term "progressive granulomatous ulceration." It has to be differentiated from nasal ulceration due to syphilis, tuberculosis, malignancy, agranulocytosis, the mycosis and myiasis group, yaws or framboesia, leprosy, rhinoscleroma, leishmaniasis, rhinopharyngitis mutilans (gangosa), and trophic post-cnecephalic ulceration. In six out of the seven cases in which the results of bacteriological investigations were available, the presence of a streptococcus in association with a

staphylococcus was reported. All local applications and internal medication proved unavailing. Radium treatment was employed in two cases with indefinite results, but deep radiotherapy (tried in one instance) seemed to promise more success, and, in the opinion of the author, deserves further trial. Eight patients died from the direct effects of the disease—namely, septicæmic cachexia and repeated hæmorrhage. One survived for four months after local cure before succumbing to generalized sarcomatous entis, and one patient died from an atypical form of "miners' phthisis" four years after recovery from the local affection. The earliest symptom is a stuffiness in the nose accompanied by a watery or sero-sanguineous discharge, but with no local pathological change. This is followed by definite nasal obstruction and a purulent or sanguineo-purulent discharge with an offensive smell. The disease then tends to spread from the interior of the nose to the outside, ulcerating the surrounding tissues progressively.

Obstetrics and Gynaecology

100 Construction of Artificial Vagina

G. GAMBAROW (*Zentralbl. f. Gynäk.*, October 28th, 1933, p. 2559) states that formation of an artificial vagina by Schubert's method (from large intestine) is less dangerous than by Baldwin's (from small intestine) but not without mortality. The skin-flap operation of Kirschner and Wagner is safe but far from simple. In Gambarow's clinic a simple operation was successful in one case. Into the wound cavity in the dissected space between bladder and rectum Hegar's dilator 26 was introduced and left for six hours on twenty-eight days following operation. Four months later the vagina, 8 to 10 cm. long, was lined by granulation tissue in the upper half at least. Eight months later the vagina was lined by normal mucosa. Two years later the patient began to menstruate, and eventually became pregnant, a communication having established itself between the artificial vagina and the cervix uteri.

101 Abnormalities of Fallopian Tubes

V. LE LORIER and G. DURANTE (*La Gynéc.*, October, 1933, p. 529) describe the various causes and the appearance and importance of cavities in the neighbourhood of the Fallopian tubes. These comprise: (a) Congenital malformations—(1) a tube doubled for part of its length, both limbs being patent throughout; (2) a depression or sacculus in an otherwise normal tube; (3) doubled tubes blind at one or both ends, each with its own distinct fibro-muscular wall. These latter are true diverticula. (b) Acquired multiple tube formations. These are shown, in an interesting series of sections, to begin by adhesion of one fimbria to a point on the mucous membrane of the inflamed tube wall. The process may extend for a considerable distance along the lumen, forming a septum, which becomes organized and lined with an extension of the tubal mucous membrane enclosed. Hence the possibility of confounding such an occlusion with an endometrioma; the distinction is made by serial sections, which show that the wall of the secondary tube is merely a septum-lined by mucous membrane on both sides. The incidence of such acquired doubling of the tubes is said to be much greater than is usually believed, because serial sections are needed for their demonstration. They are a potent cause of ectopic gestation; when the latter occurs decidual reaction is marked in the secondary cavity as in the uterus, but absent from the true Fallopian tube. H. v. KNORRE (*Zentralbl. f. Gynäk.*, November 11th, 1933, p. 2662) discusses the significance of congenital abnormalities of the Fallopian tube as a possible cause of obstruction favouring ectopic gestation. Like Markoff, he found occasional apparent evidence of tubal occlusion by inflation with air of the foetal or infantile tube in the cadaver. Evidence of occlusion was less frequent, however, after bilateral salpingectomy, and in apparently

impermeable tubes retrograde inflation from the abdominal ostium was successful, microscopical sections showing no obliteration of the lumen. Zocchi's histological examinations gave a similar result. It is concluded that congenital atresia is unimportant as a cause of tubal pregnancy, and that impermeability to air is due to a valve-like action of the folds of mucous membrane.

102 Sterilization in Germany

L. NÜRNBERGER (*Med. Klinik*, November 3rd, 1933, p. 1503) discusses practical gynaecological problems which will arise from the German law, coming into force during this year, authorizing compulsory sterilization of those suffering from certain congenital and hereditary defects. The decision of a commission of two specially appointed medical members and one presiding judicial member will authorize sterilization against the will of the person concerned. Haemophilia and hereditary skin affections, such as epidermolysis bullosa, are excluded from the scope of the statute, which is unconcerned also with induction of abortion in those subject to hereditary disease, or abortion or sterilization for social or purely medical reasons. It appears that if medical considerations call for induction of abortion or Caesarean section in those suffering from the specified hereditary disorders, to follow up the operation by tubal sterilization will be illegal. No allusion is made in the statute to the age at which legal sterilization may be performed, and x-ray castration is not mentioned in it. Operative removal of the ovaries is excluded from the scope of the new enactments, and is only to be done when life or health is seriously threatened, and then not without the patient's consent. It would thus appear that the operative sterilizing procedure in the female must not be such as to cause castration, but to prevent union of the male and female germinal cells. Reviewing such operations, Nürnbergger concludes that none is absolutely certain as regards the induction of permanent sterility, but that the following, in the order named, are most likely to be effective: (1) wedge-shaped excision of the fundus uteri with removal of both Fallopian tubes; (2) deep wedge-shaped excision of both tubes from the uterus with careful peritonization subsequently; and (3) transplantation of both tubes with their fixation in the inguinal canal.

Pathology

103 Bactericidal Action of Ketonic Urine

In pyelitis the institution of a ketogenic diet often results in the speedy disappearance from the urine of the bacteria and pus provided that a sufficiently intense ketosis is induced. A. T. FULLER (*Biochem. Journ.*, vol. xxvii, No. 4, 1933, p. 976) attempted to isolate and identify this bactericidal agent, and reports investigations which indicate l-β-hydroxybutyric acid. The inhibitory power of this acid was found to increase steadily and considerably as the urine reaction became more acid. Fuller concludes, therefore, that acidifying salts should be given in association with the ketogenic treatment. Aceto-acetic acid and acetone were found to have a similar but much weaker effect of this kind. The steps in the research are described. Since the estimation of β-hydroxybutyric acid is a very lengthy process compared with the colorimetric method for aceto-acetic acid, the determination of the amount of the latter present is commended as a sufficiently sensitive guide to the efficacy of the treatment. The author's results support to some extent the observation of Helmholtz that ketonic urines are inactive at reactions more alkaline than pH 5.6.

104 Actinobacillosis in Man

D. C. BEAVER and L. THOMPSON (*Amer. Journ. Path.*, September, 1933, p. 603) draw attention to the condition of actinobacillosis, which, while very common in cattle, has rarely been diagnosed in man. The case they now report is the third in the literature, and is of particular interest in that it proved fatal, and a pathological study at post-mortem was carried out. The patient was an

adult male who, after losing weight for about six months without apparent cause, developed symptoms of pneumonic consolidation. Death occurred after a fortnight's acute illness. At necropsy there were multiple firm greyish nodules, measuring 2 to 5 mm. in diameter, throughout both lungs. Some of them contained thick yellowish pus, whereas others were composed of greyish consolidated or caseous material. The spleen was enlarged, and was composed mainly of multiple discrete sharply circumscribed greyish-yellow lesions, 1 to 10 mm. in diameter. Lesions were observed in the liver similar to those in the spleen, though they were less numerous and somewhat smaller. One very small abscess was present in the cortex of the left kidney. Other organs appeared to be normal. Histologically, the lesions consisted of necrotic foci surrounded by granulomatous proliferative changes. Blood culture made twenty-four hours before death yielded a Gram-negative non-motile bacillus, forming acid in glucose, maltose, mannite, and salicin, producing indole, proving highly virulent to rabbits and guinea-pigs, and bearing a close resemblance to *Actinobacillus lignieresii*. The method of infection was not determined.

105 Bacteriology of Acute and Chronic Appendicitis

R. BURIAUX and J. TIPREZ (*C. R. Soc. de Biol.*, 1933, No. 29, p. 133) examined thirty-three appendices removed surgically for acute or chronic inflammation. The organ was removed aseptically, taken to the laboratory, opened up throughout its whole length, and washed thoroughly with several changes of Locke's solution. The mucosa was scraped, the scrapings were suspended in Locke's solution, and cultures were made from this suspension on litmus lactose agar plates for aerobic bacteria, and in glucose broth containing minced brain for anaerobic bacteria. The following organisms were recovered: *B. coli*, thirty times; enterococcus, thirteen times; streptococcus, twelve times; Morgan's bacillus, eight times; *Cl. welchii*, three times; *Ps. pyocyanea*, three times; *B. friedländer*, twice; *B. proteus*, twice; and *B. faecalis alkaligenes*, twice. This study reveals the almost constant presence of *B. coli* in appendicitis, and the part played by streptococci and by Morgan's bacillus in severe cases. The streptococci were of a type that grew better under anaerobic than under aerobic conditions—at least in primary cultures. They were found only in severe cases in which the appendix generally showed macroscopical lesions. Morgan's bacillus seemed to be associated with haemorrhagic lesions, sometimes going on to perforation. In two cases in which perforation occurred this organism was found in the appendix and in the surrounding abscess. One of these cases, from which Morgan's bacillus was isolated in pure culture, was complicated by general peritonitis.

106 A Test for Subclinical Scurvy

G. DALLDORF (*Amer. Journ. Dis. Child.*, October, 1933, p. 794) suggests that capillary resistance, as estimated by Hecht's method, may be used to reveal the existence of early or slight degrees of scurvy at a time when no clinical manifestations are observable. Reviewing the literature, he quotes Göthlin's observations (*Scandinav. Arch. f. Physiol.*, 61:225, 1930) to the effect that 18 per cent. of a group of poorly fed school children had an abnormal capillary fragility (which disappeared on the addition of orange to the daily diet), and that two patients, who, intentionally deprived of vitamin C, developed the sign of fragility, lost it when orange juice was given. In Hecht's test negative pressure is applied to the skin, and the point at which petechiae appear is noted. A serious limitation is that individual variations are very common; a single test is therefore of little value. Changes in the capillary resistance in individual cases or differences in average values of groups have, however, some diagnostic significance. In a group of children from poor homes the incidence of subclinical scurvy was found by this procedure to be between 35 and 66 per cent. The correction of dietary deficiencies was promptly followed by improvement in the capillary resistance. According to Dalldorf, no dietary factor other than vitamin C is known to influence the capillaries.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

Cardiac Infarct

107

J. HOCHREIN (*Münch. med. Woch.*, October 20th, 1933, p. 1613), after carefully tracing the history of seventy cases of this condition, found that cardiac infarction occurs four times more frequently in men than in women, and tends to appear after the fourth decade. Subjects whose daily life involved considerable emotional or nervous stress were more liable to coronary stenosis and its consequences (business men, academic workers, signalmen, etc.). In 40 per cent. of the cases it was possible to elicit a family history of cardiovascular disease; in 25 per cent. a history of rheumatism was obtained; in syphilis and gonorrhoea, diabetes and gout played no significant part in the aetiology. In only 25 per cent. of his cases did the author find that the attacks occurred without previous warning; the remainder gave a history of unusually great dyspnoea after slight physical effort, and showed signs of circulatory insufficiency (oedema, ascites, etc.). In 25 per cent. of his cases symptoms of anginal attacks had appeared long before the establishment of the infarct; in many, lesser symptoms of cardiac trouble had been complained of but ignored. Myocardial infarcts were found to be specially frequent in November, December, and January, and were not the unexpected phenomenon described in textbooks. Hochrein believes that psychological factors are of definite importance in the precipitation of the condition, and quotes two illustrative cases. He discusses preventive treatment with nitrates and organ extracts in the untoward symptoms which often occur. Special warning is given against digitalis unless some cardiac decompensation is diagnosed. The value of sedatives is specially dealt with; the author favours barbiturates, and considers morphine derivatives contraindicated. Diet should be of small volume or high calorie value; smoking must be forbidden, as must also coffee or tea; alcohol in small doses is often useful; physical exertion must be controlled according to the general condition of the heart. Atropine, recommended by some, was found by the author to be of little avail.

108

Atherosclerosis

H. GROLL (*Med. Welt*, October 21st, 1933, p. 1485) divides atherosclerosis into the typical atheroma, as seen in the aorta, coronary, and cerebral arteries; medial calcification, especially common in the femoral arteries; and diffuse hyperplastic arteriosclerosis, such as accompanies hypertension. After discussing the histological picture in these conditions he summarizes the present knowledge regarding the aetiology of atherosclerosis. A mechanical factor is frequently present, such as apparently determines the localization of atheromatous patches—for instance, around the mouths of the intercostal arteries—while age is another predisposing cause. Diathesis he considers important, and cites the plethoric type in which all mesenchymal tissues tend to degenerate; the nervous individual with an unstable vasomotor system is also peculiarly liable to arterial disease. Metabolic dyscrasia may play a part, as suggested by the production of fatty changes in the intima of the aorta of guinea-pigs on a high cholesterol diet. This has caused Aschoff to suggest that atheroma is due to an imbibition of lipid in guinea-pigs by a high calcium diet or by injection of adrenaline. In the latter instance it appears to be secondary to angiospasm. It is not known whether hypercalcaemia in the human being will produce it. Further factors are endogenous and exogenous toxic-infective influences, among which may be cited lead, alcohol, nicotine, diabetes mellitus, gout, and nephritis. The part played by syphilis has, he states,

been exaggerated in the past, but other infections such as rheumatic fever may be of importance. Confusion has, he believes, originated in the past from the different viewpoints from which this protean disease may be regarded. Its segregation from other arterial disease is important—fron, for instance, Buerger's disease, endarteritis obliterans, and periarteritis nodosa acuta. Groll further concludes that Monkeberg's medial calcification and diffuse hyperplastic arteriosclerosis should probably not be included under the heading of atherosclerosis.

Diphtheria in Immunized Persons

109

W. DOOLIN (*Irish Journ. Med. Sci.*, November, 1933, p. 611) records his observations on seventy-eight cases certified to be suffering from diphtheria, which occurred among 8,027 children, 6,878 of whom had been fully, and 1,149 partially, immunized. In thirty-three cases (42.3 per cent.), however, the diagnosis was not confirmed, but the treatment had been incomplete, and in six cases the diagnosis was confirmed and the treatment had been complete, but the latent period had been insufficient for development of immunity—that is, had been under four months—so that in only twenty-seven cases had the diagnosis been confirmed, the treatment complete, and the time factors fulfilled. In nine of the twenty-seven cases the diagnosis was extremely doubtful, and in four others doubtful. Of the remaining fourteen cases twelve had not been Schick-tested after treatment. Diphtheria was reported in seven Schick-negative reactors, but in five of these the diagnosis was extremely doubtful, and two negative reactors developed definite diphtheria. All the seventy-eight patients recovered. In all the cases response to antitoxin was rapid, and in only one instance did complications occur (in the form of cardiac irregularity).

Trichlorethylene Industrial Poisoning

110

K. ROHOLM (*Ugeskrift for Læger*, November 2nd, 1933, p. 1183) draws attention to the growing popularity in Denmark of the fat-solvent trichlorethylene ($\text{CHCl}_2\text{CCl}_3$) as a cleansing agent. He states that it is dangerous, and recalls that in 1931, in Germany, Stüber published 284 cases of poisoning, among which there were twenty-five deaths. The author gives an account of three cases of acute, but not fatal, trichlorethylene poisoning in a factory where, in December, 1932, three apprentices between the ages of 15 and 16 were set to work to clean walls and machinery soiled with oil. The trichlorethylene with which they mopped up the oil was served to them in cans. One after the other the boys collapsed, and had to be taken to hospital. A fourth case was that of a workman, aged 21, who cleaned machinery with trichlorethylene in a room with doors and windows shut. Though he was ill enough to be taken to hospital, he recovered quickly. Not being inflammable, and being a more effective solvent of fats than benzine, trichlorethylene has become popular both in factories and in the home. According to Roholm, its dangerous qualities are inadequately appreciated, and it is not generally realized that some persons, notably women and children, are particularly susceptible to this poison. T. CHRISTIANSEN (*ibid.*, p. 1187) records a case of a woman, aged 30, admitted to hospital with the diagnosis of military tuberculosis of the lungs. She had been ailing for a couple of months, and a skiagram of the lungs had led to a diagnosis of trichlorethylene poisoning. During eighty-one days' residence in hospital the lung shadows cleared up completely. It transpired that the patient's first symptoms of serious pulmonary disease had begun after she had spent half an hour cleaning shoes with trichlorethylene close to a very hot stove.

Surgery

111

Femoral Hernia

L. RONSE (*Journ. de Chir. et Ann. Soc. Belge de Chir.*, October, 1933, p. 306) suggests that the causation of femoral hernia may be similar to that which produces diverticula of the oesophagus. In the latter case inflammation of the peribronchial glands brings about the formation of adhesions between the glands and the oesophagus; which, by means of traction, produce a diverticulum. Three cases are reported in which operative treatment disclosed a similar condition. In each instance there was a history of adenitis which had subsided, leaving a femoral hernia. Operation showed a hernial sac which was firmly adherent to one or more glands in the crural canal. It is pointed out that all the lymphatics of the lower limbs, the external genitals, and the anus drain into the inguinal glands. There are many causes of inflammation in these glands, particularly in the female, which accounts for the greater frequency of femoral hernia in women. In chance of the cervix it is usually the inguinal and not the pelvic glands which are affected. The result of inflammation in these glands is that the tissue in this region is replaced by a mass of scar tissue, which contracts round the glands, particularly when the gland of Cloquet is involved, and produces a hernia by traction. It is therefore suggested that all cases of non-suppurative adenitis of the inguino-crural glands should be excised to prevent the later formation of a hernia.

112 Recurrent Dislocation of the Shoulder

P. EWALD (*Zentralbl. f. Chir.*, October 28th, 1933, p. 2564) states that in Germany; but not in Austria, those who habitually dislocate a shoulder are entitled to compensation which is correlated with the trauma, possibly very slight, which preceded the original dislocation. This, he thinks, is unjust; although some cases of habitual dislocation are due to accidental tearing of the capsule or detachment of the supraspinatus muscles from the greater tuberosity, many are due to congenital or non-traumatic slackness of the capsule. Ewald states that he has seen and radiologically demonstrated in school children the occurrence of subglenoid dislocation of the humerus of one side during gymnastic movements of the arms upwards. He relates the case of a man, aged 33, who returned to work ten days after the reduction (in narcosis) of his first dislocation of the left shoulder following slight trauma; during the next three years displacement occurred on innumerable occasions, even during sleep, but with one exception was rectified by the patient himself. Radiological appearances were normal, but an operative tightening of the capsule was undertaken. Responsibility for the 30 per cent. incapacity which followed was laid—wrongly, as Ewald thinks—on the original accident.

113 Malignant Tumours of Long Bones

F. ROSCHER (*Norsk Mag. f. Laegevid.*, October, 1933, p. 1081) records his observations on twenty-two cases of malignant tumours of long bones treated in Professor B. Bull's service of the Rikshospital, Oslo, from 1913 to 1928. There were seventeen cases of primary sarcoma and five of metastatic bone tumour. In the first group the humerus was affected in seven, the femur in eight, and the tibia and fibula in one case each. Seven of the primary sarcomas were observed in women and ten in men, seven of them being probably medullary and five probably periosteal sarcoma. In five cases it was impossible to ascertain their starting-point. Of eleven tumours of the humerus seven were primary sarcoma and four metastatic tumours. Four of the patients with primary sarcoma of the humerus were still in their teens, whereas three were aged from 28 to 55. In three cases there was a history of trauma. All these tumours were localized in the upper third of the humerus. Treatment was operative in every case. In six cases humerus resection and

fibular transplantation were performed. One of the femoral tumours consisted of a metastasis from a hypernephroma. Six of the femoral cases occurred between the ages of 13 and 20, one was aged 29, and another 63. Roscher comes to the conclusion that radical amputation and exarticulation—at any rate in the case of the femur—not infrequently saves the patient's life, whereas resection very rarely produces a good result. Every case of resection should subsequently be treated by x rays.

114 Foreign Bodies in the Alimentary Tract

G. STOEL (*Nederl. Tijdschr. v. Geneesk.*, November 15th, 1933, p. 5274) states that during the period 1930-3 fifty-four patients were admitted to the Coolsingel Hospital, Rotterdam, with the diagnosis of foreign body in the alimentary tract. This number was almost twice as great as that of the admissions for foreign bodies in the respiratory tract. There were thirty-two males and twenty-seven females, and the ages ranged from under 1 to over 70. In fifty-three instances the diagnosis of foreign body was confirmed, the site being the oesophagus in twenty cases, the stomach in six, the duodenum in five, the colon in seven, the rectum in two, and the intestines (without mention of the exact situation) in thirteen. Of the twenty oesophageal cases, seven underwent oesophagotomy; in six the foreign body was extracted by mouth, with or without oesophagoscopy; in six it was passed by rectum; and in one the patient died without having had treatment. Of the thirty-three cases twenty-two had conservative treatment and the foreign body was passed per rectum, in two it was extracted, and nine underwent operation. The operative mortality was nil.

Therapeutics

115 Quebrachitol as a Sugar Substitute in Diabetes

R. A. McCANCE and R. D. LAWRENCE (*Biochem. Journ.*, vol. xxvii, No. 4, 1933, p. 986) have tested the value of quebrachitol (1-methylinositol) isolated from quebracho bark as a sweetening agent for diabetic patients. They found that when taken by the mouth it does not relieve hypoglycaemia, raise the blood pressure, or lead to the deposition of glycogen in the liver. It is much less sweet than cane sugar, and consequently larger amounts have to be taken. Such large doses produce colic and diarrhoea, which may be severe. The authors are therefore unable to recommend this drug as a sugar substitute.

116 Intravenous Liver Extract Therapy in Pernicious Anaemia: Assessment of Potency

F. H. BETHELL and S. M. GOLDHAMER (*Amer. Journ. Med. Sci.*, October, 1933, p. 480) compare the reticulocyte response induced in pernicious anaemia respectively by the customary doses of orally administered liver extract and desiccated stomach (ventriculin) and the intravenous injection of liver extract. Minot and his associates showed that the degree of response was uniform and predictable in relation to the erythrocyte count before treatment with liver. Subsequently, the daily determination of the reticulocyte percentage until a maximum value is obtained has been the generally accepted means of assaying the potency of other modes of treatment proposed for this condition, and a formula was designed to indicate the magnitude of response for liver therapy. There followed another one designed to give corresponding information in the case of stomach extract therapy. When a formula was calculated on these lines for liver injection therapy, it was found that the reticulocyte response was of considerably greater magnitude than in the cases of the orally ingested liver or stomach treatments. The authors suggest that the probable significance of the different degrees of response on the part of the reticulocytes is that it reveals the rate at which the potent material travels to the bone marrow. It is not, they believe, connected with the total amount of potent

material administered to the patient. The oral route is rendered of less value probably by the occurrence of incomplete absorption from the gastro-intestinal tract, or partial destruction by digestion. Tables of normal "reticulocyte response" are provided by the authors as standards in evaluating the potency of liver or stomach preparations. A maximum percentage which was significantly low would indicate that the therapeutic preparation was of inadequate potency, or that there was present an infection preventing proper response, or that absorption was incomplete, or that the patient had arteriosclerosis.

117 Medical Treatment in Obstructive Cholelithiasis

According to J. DIMITRESCO-POPOVICI (*Presse Méd.*, November 8th, 1933, p. 1730) operation should be performed in lithiasis of the common bile duct only after sure diagnosis; the latter is, however, often difficult as the clinical and radiological signs are not always sufficiently clear. Duodenal tubage with instillation of a 33 per cent. solution of magnesium sulphate has been proved a better diagnostic aid than the icterus syndrome or the history of previous attacks. As the procedure causes a discharge of bile in cases of icterus of obstructive origin, the author believes that it may be a curative measure in calculous obstruction of the duct. Two cases are cited which substantiate this opinion; in a third a simple attempt at gastric tubage provoked a biliary attack with a bile syndrome, which was followed by discharge of two calculi. The mechanism of the action of duodenal tubage has been experimentally proved as follows. The presence of the chologogue in the duodenum is followed by a period of muscular tetany, more or less prolonged, and accentuated according to the degree of irritability of the substance instilled. This is followed by peristaltic and anti-peristaltic contractions of varying violence related to the same cause. These are immediately followed by a period of duodenal distension, which relaxes the sphincter of Oddi and withdraws the pancreatic juice and bile of the ducts. Once the ducts are emptied the gall-bladder discharges its contents owing to the aspiration provoked by the duodenal contractions. Relaxation of the sphincter, above which calculi are usually impacted, and the subsequent rapid duodenal evacuation are the two factors in clearing the duct. The author suggests, in explanation of this mechanism, that the gall-bladder alone, by its reflex contractions, is capable of responding to the magnesium irritation; in biliary lithiasis it is atonic, and consequently incapable of contracting and expelling its contents.

118 Simultaneous Bilateral Artificial Pneumothorax in Pulmonary Tuberculosis

G. BARBERA (*Il Polichinico, Sez. Prat.*, November 20th, 1933, p. 1841) records twelve illustrative cases in patients aged from 17 to 31, suffering from very severe forms of pulmonary tuberculosis, who were treated by simultaneous bilateral artificial pneumothorax. The treatment was well tolerated in each case, the end-results after a period ranging from two to six years being as follows: one death, no change in two cases, improvement in five cases, and clinical recovery in four.

119 Immunization against Whooping-cough

L. W. SAGER (*Journ. Amer. Med. Assoc.*, November 4th, 1933, p. 1449) states that a *B. pertussis* vaccine containing 10 billion bacilli per c.c.m. made from recently isolated strongly haemolytic strains was injected into 394 young non-immune subjects. A total of 7 to 8 c.c.m. was divided into three weekly (bilateral) injections of 1, 1.5, and 1.5 c.c.m. respectively. Of the injected children twenty-nine were exposed throughout all the stages of pertussis, but none contracted the disease, whereas thirty-one control children in twenty-four families developed whooping-cough. None of 162 children accidentally exposed had a cough which in any way resembled pertussis. Active immunity was completed in four months and lasted for years. The best age for immunization is stated to be the second half-year of life.

Radiology

120

Duodenal Diverticula

C. D. COSTELLO (*Brit. Journ. Radiol.*, October, 1933, p. 577), reporting six cases of diverticulum of the duodenum, comments on the detection of this condition by the barium meal. In four of his cases the diverticula were not observed until after more than one barium meal, and in none were the findings complete. The reason for this was that in every case the indication of the diverticulum was only found on the films taken, and had not been shown by the screen examination. The author remarks that the stomach and the first part of the duodenum take up so much of the examiner's attention that the second, third, and fourth portions tend to be neglected, especially since the symptoms may be misleading. The possible occurrence of diverticulosis should be definitely considered, therefore, at every screen examination, the patient being tested in the erect and the prone positions in all cases. The shadow of the barium meal in a duodenal diverticulum is usually rounded and smooth, both in filling and in outline. The shadow is distinct from that of the duodenum, but a definite connexion can nearly always be traced by following the folds of the mucosal relief into the diverticulum, and by emptying the duodenum by palpation under the screen. According to the author it is important to determine the exact site of a diverticulum, since the nearer to the major papillae it lies the smaller will be the size at which it will press upon the ducts entering there. Differential diagnosis from the niche of gastric or duodenal ulcer, or a colonic haustrum or diverticulum, is, he states, not difficult.

121

Interpretation of Duodenal Motility

N. S. ZEITLIN (*Radiology*, October, 1933, p. 337) record conclusions drawn from the examination of over 2,000 cases of disturbances of the motility of the duodenum, the flow of the barium meal being watched, and careful note being taken of the size of the duodenal cap, the angle formed by the cap and the descending portion, the course over the spine, the length and steepness of the ascending portion, and the angle at the duodeno-jejunal junction. Normal hypotonic and hypertonic cases were used as controls. It was found that duodenal ulcer, gastric ulcer, and pathological conditions of the gall-bladder did not affect normal stasis and surging. Zeitlin satisfied himself that mechanical obstruction alone does not account for either the x-ray signs or the clinical symptoms. Many of the symptoms of dyspepsia have been attributed by other authors to duodenal surging, but no confirmation of this was obtained. Zeitlin believes that this phenomenon, as well as that of stasis, is of physiological origin, being due primarily to the neuromuscular mechanism, and secondarily to the mechanical conditions found variously in different types of patients. He thinks he has obtained sufficient evidence to justify the view that this symptom-complex is due to the lowering of the threshold of the sympathetic sensation centre. He examines critically and rejects other explanations, such as acute angulation at the duodeno-jejunal junction, compression by the mesenteric artery, and duodenal inflammation or intermittent obstruction. He is doubtful whether the symptoms noted in such cases have any direct relation with the duodenal condition.

122 Pyrexial Treatment of General Paralysis

WAGNER-JAUREGG (*Wien. med. Woch.*, Nr. 1, 1934, p. 11) criticizes on various grounds the treatment of general paralysis by short-waved high-frequency currents timed and graded so as to induce a temperature curve resembling that of malaria. This treatment is given on the assumption that the success of artificially induced malaria in cases of general paralysis depends mainly or exclusively on the fever provoked. This assumption is incorrect, for an artificial malaria may be afebrile, or nearly so,

and yet the results are beneficial. Many such cases have been recorded. Their number would be even greater were it not that in some cases the absence of a febrile reaction was promptly interpreted as a failure to induce malaria, and some other treatment aiming at raising the temperature was tried. Good results have, it is true, been claimed for the high-frequency treatment of general paralysis; but these results have been early and have not yet stood the test of prolonged observation. The discomforts of the high temperature induced by radiotherapy or diathermy may be even greater than those associated with malaria, for in the latter case the patient can at any rate move his limbs freely and change his position, whereas the former treatment entails eight hours of immobilization, during which the patient is strapped up like a mummy. There are two other objections to radiotherapy and diathermy—namely, the prospect of burns and the cost of the apparatus. The author professes satisfaction with the results of artificial malaria, the dangers of which he considers apocryphal, and he sees no reason why, for the present, new-fangled and costly substitutes for it should be introduced in Vienna.

Obstetrics and Gynaecology

123 Leucoplakia and Cancer of the Cervix

E. PHILIPP and G. SCHÄFER (*Zentralbl. f. Gynäk.*, October 14th, 1933, p. 2407) discuss the connexion between leucoplakia and cancer of the cervix. Hinselmann, working with the colposcope, which he introduced, has stressed the importance of leucoplakia and described five or six varieties; he regards it as a precancerous condition, and believes that he has found behind a leucoplakia an early carcinoma, and that serial sections of his leucoplakia show various stages of transition to cancer. Others have confirmed the first of these findings. The present authors believe that the crucial test is a clinical one—namely, is carcinoma found to occur in those who are known to have leucoplakia of the cervix? Hinselmann himself has no evidence of this nature to offer, for he removes the leucoplakias by amputation of the portio. A critical consideration seems to destroy the value of the three recorded cases in which the sequence in question has been reported. Philipp and Schäfer, who have used the colposcope for some three years and are convinced of its diagnostic value, have followed up for from six to thirty months forty-nine cases of cervical leucoplakia, but in no instance have they yet noted the development of a carcinoma. In colposcopy, they suggest, erosions deserve particular attention, the occasional formation of a carcinoma in an erosion being undoubted.

124 Late Effects of Pregnancy Toxaemia

M. D. ARWYN EVANS (*Journ. Obstet. and Gynaecol. British Empire*, October, 1933, p. 1024) reports research work on the subsequent effect of a pregnancy toxaemia. The term was taken to cover cases of low reserve kidney, pre-eclampsia, and eclampsia. In round numbers two out of every three cases with albuminuria during pregnancy develop after-effects, mostly renal. Twenty per cent. developed chronic nephritis, so that this becomes a more important consideration than eclampsia, which is generally preventable. Prognosis may be based on the facts that the average age of the non-toxaemic patients was 26.5 years; of the albuminuric, 28.4; and of those who developed a definite renal lesion within four years 28, a doubtful renal lesion 31, and no renal lesion 26 years. Ultimate prognosis was found to be more favourable in primigravidae than in multiparae, but more important was the duration of the albuminuria. This averaged fifteen days in a group of patients who developed no after-effect and twenty-eight days in those classed as probably chronic nephritic—from which is deduced the teaching that albuminuria must be watched for and treated fully by diet and bed, and that if it persists over

a fortnight induction must be considered, as also if blood pressure remains above 170 mm. Hg. In patients with albuminuria present at their discharge two-thirds developed chronic nephritis. Therefore a mother must be kept in bed until there is no albumin in the urine. The presence of headache and eye signs suggests the possibility of permanent damage, but the position and degree of oedema, amount of albumin, and the presence or absence of casts seemed to bear no relation to the prognosis. In the multiparous patients studied 25 per cent. had had previous albuminuric pregnancies. Searching for data for prognosis of recurrence, the author found that this was likely to occur in patients, aged 28 or over, when the albuminuria had lasted twenty-one days during the pregnancy, when the blood pressure had averaged over 160 mm. Hg, and when albuminuria was still present on discharge. If the child survived for fourteen days its future prognosis was good.

Pathology

125 Haemolytic Streptococci grown Anaerobically

R. M. FRY (*Journ. Path. and Bact.*, November, 1933, p. 337) draws attention to an important fallacy in the routine examination of clinical material for β -haemolytic streptococci. During the last three years he has observed a number of cases in which a streptococcus has been isolated that gave green colonies when grown aerobically and typical β -haemolytic colonies when grown anaerobically. In some of these cases β -haemolytic streptococci had been isolated in pure culture from the blood, and the anomalous forms were subsequently grown from the site of inflammation in the cervix uteri. This circumstance inclines the author to discountenance the possibility of a mixed infection with α - and β -haemolytic types, and to regard the anomalous strains as merely reacting differently to different environmental conditions. Further evidence in favour of this view is afforded by the fact that the aerobic green forms produced a strong haemolysin when grown in serum broth, and that one particular strain, in apparently pure culture, gave constantly green colonies under aerobic and β -haemolytic colonies under anaerobic incubation. Practically, it is desirable to put up material suspected of containing streptococci under both aerobic and anaerobic conditions.

126 The Sedimentation Rate in Scarlet Fever

S. FRIEDMAN (*Amer. Journ. Med. Sci.*, November, 1933, p. 683) made a study of the sedimentation rate in fifty-five cases of scarlet fever in patients aged from 4 to 55 years with the following results. In very mild cases which showed no fever or constitutional symptoms there might be no increase of the rate at any time. In ordinary mild cases the rate was elevated at first, but fell fairly promptly and reached a normal level during the second week of the disease. In severe cases the rate remained at a high level throughout the patient's stay in hospital. Complications were accompanied by a rise in the rate unless the rate was already distinctly increased. No conclusions could be drawn as to the effect of the administration of convalescent serum or antitoxin on the sedimentation rate.

127 Oxaluria and Intestinal Tuberculosis

V. GIUDICEANEA (*Il Policlinico, Sez. Prat.*, November 6th, 1933, p. 1755) records a series of personal cases in which oxaluria was associated with the presence of small intestinal parasites, such as ciliomastix, various amoebae, trichoccephalus, and lamblia. He considers that the frequency of this association is due to changes in intestinal chemistry and to the toxic action on the hepatic function and metabolism. He admits, however, that this is only one of the possible explanations of oxaluria, which may also be regarded as a primary change in metabolism or as one occurring in various morbid conditions, especially gastric hypochlorhydria.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

128

Collapse in Diabetic Coma

For some years M. LABÉÉ and R. BOULIN (*Presse Méd.*, November 4th, 1933, p. 1705) have believed that collapse is a pathogenic factor in certain acidotic diabetic comas, and must be regarded as an important cause of mortality. It occurs not only in old subjects with impaired myocardia, but also in the young who have no reason to fear cardiac failure. Collapse rarely occurs at the onset of the coma with the somnolence, but usually six to twelve hours later, and it may be delayed for thirty-six hours. Functional premonitory symptoms (malaise, dyspnoea) are absent; anuria or extreme oliguria, associated with a lowered arterial tension, is a precursor of it, and sometimes of its complication with renal insufficiency. The chief symptom of collapse is hypotension: the maximal tension rapidly and progressively falls; the minimal, often difficult to measure, falls less quickly at the onset. The pulse, when palpable, is always perfectly regular, but accelerates with the collapse. The heart is seemingly little affected, the sounds remaining fairly strong and not markedly muffled. Gallop bruits, functional souffles, and arrhythmia have never been noted. In view of the cardiac conditions, Lewis, who reports two cases of cure, believes that the collapse is due to dehydration consequent on the precomatose polyuria, vomiting, and diarrhoea, and advocates rehydration with large intravenous injections of hypertonic saline serum. On the same grounds, however, the present authors, believing that the collapse is peripheral rather than central, vascular rather than cardiac, administer adrenaline. Citing two personal cases of cure, they emphasize the importance of estimating the arterial tension during the first and succeeding days of the coma. If this falls progressively, intramuscular injections of adrenaline, or oral doses (2 to 5 cg.) of ephedrine, are given prophylactically. If the maximal tension falls below 9 cm. an intravenous injection of 1/2 litre of physiological serum containing 1 mg. of adrenaline is given, and repeated once or oftener if necessary. Should the fall continue during the ensuing days daily muscular injections of adrenaline, or preferably ephedrine tablets, are given.

129

Toxicity of Carbon Tetrachloride

J. W. TOMS and M. M. HELSY (*Journ. Trop. Med. and Hyg.*, November 1st, 1933, p. 334) point out that carbon tetrachloride and its closely allied halogen derivatives of the aliphatic hydrocarbons are capable, even in therapeutic doses, of causing fatal intoxication, accompanied by acute degeneration of the liver. Fatalities from this cause occur much more frequently among children and adolescents than among adults, probably owing to the deficiency of calcium reserves in the young. Immediate poisoning by carbon tetrachloride in therapeutic doses is generally associated with disease of the liver, or with some other clinical contraindication to the exhibition of the drug. Delayed poisoning is generally due to non-elimination of the drug from the intestinal tract, in or without association with clinical contraindications. It can be obviated, where the liver is healthy, by rapid and free evacuation of the drug. In Egypt fatal poisoning by carbon tetrachloride has been found to be closely associated with ascariasis, which would appear to act in two ways. It may cause a mechanical obstruction to be presented to the action of the saline purgative, and increased obstruction of the drugs where worms are numerous in the intestine, through aggregation of the worms into clumps. It may also diminish the natural resistance to the drug in cases where clinical contraindications already exist, either through toxins produced by the worms or in consequence of the unsatisfactory conditions and consequent low state of the general nutrition which ascariasis implies. Where intoxication by carbon tetrachloride has

begun, intensive treatment by intravenous injections of calcium gluconate may save life, provided that the drug has been thoroughly evacuated from the intestinal canal. The authors add that the traces of carbon disulphide found in medicinal carbon tetrachloride are of no toxicological significance.

130

Rheumatism and Environment

G. EDSTRÖM (*Hygiea*, November 15th, 1933, p. 801) publishes statistics dealing with the incidence of rheumatic diseases among the municipal employees of Gothenburg in the period 1928-32. Accidents excluded, the rheumatic diseases accounted for 11.6 per cent. of all the sickness days. A classification of the employees according to their work showed that the incidence of rheumatic diseases was much higher among outdoor than indoor workers. The rheumatic diseases were classified according as they affected the joints or other structures, and it was found that muscular rheumatism and neuralgia accounted for many more sickness days than did articular rheumatism. Thus, among the outdoor employees of the harbour service there were only sixteen sickness days per 100 employees every year due to articular rheumatism, whereas the corresponding figure for muscular rheumatism and neuralgia was 104. So, though articular rheumatism may be practically the only form of rheumatism which inflicts permanent invalidism, it is the muscular and nerve forms of rheumatism which account for most of the sickness rate among persons not more or less permanently on the sick list. In his plea for the organization of special rheumatism services devoted to the betterment of the conditions under which persons subject to rheumatism work, the author draws attention to a statement by Mathieu Pierre-Weil in 1932 at the last Rheumatic Congress in Paris, according to which, in a large administrative railway area, a special rheumatic service had succeeded in reducing the costs entailed by rheumatism by not less than 40 per cent.

131

Tuberculosis and Chorea

E. LOEWENSTEIN (*Wien. klin. Woch.*, October 27th, 1933, p. 1286) claims to have discovered tubercle bacilli in the blood stream and cerebro-spinal fluid in several cases of chorea. He refers to his previous article (*Munch. med. Woch.*, 1931, No. 7) in which he described positive blood cultures of tubercle bacilli in four cases of chorea. The association of chorea and polyarthritis has been recognized for many years, but Loewenstein believes that "rheumatic" pleurisy, "rheumatic" chorea, and "rheumatic" iritis are actually all of tuberculous origin. "Recently, it has been recognized that 90 per cent. of cases of rheumatic iritis are tuberculous." Several German and Italian authors have confirmed the clinical connexion between tuberculosis and rheumatism, and Loewenstein states that the indisputable occurrence of tubercle bacilli in the blood stream in chorea justifies the opinion that cerebral tuberculous foci may be the origin of chorea. The scarcity of material has prevented histological demonstration, but R. LENS (*Wien. Arch. f. klin. Med.*, No. 10) described inflammatory changes in the blood vessels and in neighbouring tissues in the region of the island of Reil, the anterior cerebral ganglia, and ventral portion of the mid-brain. Loewenstein states that he has found tubercle bacilli in the blood and cerebro-spinal fluid in many cases of dementia praecox. Two cases are described. The first, a girl aged 9 years, had a positive tuberculin reaction, hilar peribronchial thickening, and calcification of lymph nodes. She was debilitated, with dysphagia, stammer, and violent choreic movements. Culture of blood and cerebro-spinal fluid showed many typical colonies of tubercle bacilli. In the second, a boy aged 11 had a negative tuberculin reaction. He was admitted with very violent choreic movements and dragging of the right leg. Though the blood cultures were negative, cultures from the cerebro-spinal fluid were positive in every instance.

Surgery

132

Bleeding from the Nipple

According to I. PHILIPOWICZ (*Zentralbl. f. Chir.*, November 4th, 1933, p. 2603) the occurrence of the malignant breast tumour after bleeding from the nipple is especially frequent among the Jewish and Eastern races. The author recounts a personal experience of eight cases, in five of which malignant disease was present, and, after discussion of the treatment, comes to the following conclusions. For the cases with quite a small palpable tumour wide excisions should be done: histological evidence of malignancy calls now for radical operation. When no tumour can be felt continuous observation should be carried out: if this is impossible, or if the patient is aged over 40, radical excision should be done. Radical treatment is required also for diffuse disease or non-limited tumour. Non-radical amputation is useless, and biopsy is dangerous as well as uncertain. According to F. KLAGES (*Monats. Krebshepfig.*, August, 1933, p. 321) the frequency of bleeding from the nipple as a symptom in cancer of the breast has been variously reported as from 0.7 to 9 per cent.; in about one in three cases of bleeding from the nipple carcinoma is present at some stage, but the bleeding may occur (in the absence of carcinoma) from an intracanalicular cystepithelioma or papillary cystadenoma, or in the "cystic breast." Vicarious mammary haemorrhage is possible. Injections, aspiration, and radiation are not justified when there is bleeding from the nipple and a tumour is present: the operation should be simple or radical, according to clinical findings, but in the former case sections should be microscoped before the operation is concluded.

133

Instrument for Suprapubic Cystostomy

M. SERRALLACH (*Journ. d'Urol.*, October, 1933, p. 360) describes a new instrument, which he calls a bistoury-harpoon, for use in suprapubic cystostomy. He points out the difficulties experienced in fat patients with small retracted bladders and the necessity for skilful technique in operating where the bladder lies at the bottom of a deep wound. The knife is made in two sections, and has the appearance of a spearhead; it divides down the middle, leaving two bistouries which are easily separated. As soon as the bladder is located with the finger and the peritoneal reflection has been separated, the knife is introduced into the bladder with a sharp cut, being guided by the index finger. The two segments of the bistoury are now separated and each point draws up an edge of the vesical incision, thus allowing the surgeon to see the opening into the bladder. It is then easy to pass a drainage tube through the opening into the bladder, which is firmly held by the two harpoons. As soon as the tube is in place the harpoon is withdrawn. By means of this instrument the author finds that difficult cystostomies are quickly and satisfactorily carried out.

134 Intussusception associated with Tuberculosis

E. EASTON (*Arch. of Surg.*, November, 1933, p. 868) describes an unusual case of intussusception which occurred in a man of 32. Operative treatment for the reduction of the intussusception was carried out and an ileostomy performed. The patient continued to lose weight and strength, and a second operation (entero-enterostomy), for the repair of the intestinal fistula, was undertaken. The patient died on the sixth day. Necropsy showed chronic active bilateral apical tuberculosis of the lungs, with bilateral, caseating, tuberculous bronchopneumonia in both lower lobes, and tuberculous pneumonia in the left upper lobe. Parenchymatous degeneration was seen in the liver and kidneys. There was also necrosis of the ileum, peritonitis of the terminal ileum and ascending colon, ulcerative tuberculous colitis, diverticula of the duodenum, and active tuberculosis of the mesenteric lymph nodes. Easton suggests that pulmonary tuberculosis is a predisposing factor in causing intussusception, and states that gastro-intestinal disturbances have been noted in 70 to 92 per cent. of cases of early

tuberculosis. Ulcers arising from typhoid fever or intestinal tuberculosis are frequent causes of intussusception, whilst trauma and diet are important causative factors. The strong, irregular peristalsis induced by castor oil is another reason given for the lesion. An enlarged tuberculous lymph gland can produce intussusception by pressure into the wall of the intestine until there is complete invagination. The disease, less common in adults than in children, shows a high mortality, which is in direct proportion to the length of time between the onset and the operative treatment. There is a tendency to recurrence even after the affected piece of intestine has been resected. Easton states that every tuberculous patient should be regarded as a potential case of intussusception, special care being taken with regard to nutrition, protection from over-exertion, and an increased watchfulness for gastro-intestinal symptoms.

135

Mesenteric Cyst

M. MILIANITCH (*Bull. et Mém. Soc. Nat. de Chir.*, November 4th, 1933, p. 1269) discusses the various methods of treatment of this rare and interesting lesion. Since puncture and marsupialization have fallen into disuse the chief ones between enucleation or intestinal resection, and the author reports the removal of a mesenteric cyst the size of a child's head by the latter method. Operation revealed a large cyst enclosed in the mesentery, situated at an equal distance from the caecum and the duodeno-jejunal angle, and intimately adherent to a large portion of intestine on one side, whilst the other was surrounded by a rich plexus of vessels. A large quantity of fluid was withdrawn on puncture. It was decided to carry out the resection of a large portion of the intestine together with the removal *en bloc* of the mesenteric tumour and a lateral anastomosis in two layers of the intestine. This was successful and the patient made a good recovery.

Therapeutics

136

Serum Treatment of Tularemia

L. FOSHAY (*Journ. Amer. Med. Assoc.*, November 4th, 1933, p. 1447) records his observations on sixty-nine cases of tularemia treated by serum made by inoculating goats subcutaneously with formaldehyde-killed suspensions of *B. tularensis*. The injections were given subcutaneously, intramuscularly, and (most frequently) intravenously. No patient was treated during the first six days of disease, five were treated on the seventh, eight before the end of the tenth day, and the majority during the first five weeks, the average time for receiving serum being the twenty-first day. Four deaths occurred. The mean duration of the disease in the sixty-nine cases was almost half that of a control series. The duration of the adenitis and period of disability were appreciably shortened, but the mean febrile period was not. Foshay recommends that in a moderately severe attack two intravenous injections should be given on successive days, of 15 c.cm. each, of an antiserum made from virulent strains of the organism. When the lymphatic glands are already larger than 5 cm. in diameter, three such doses should be given to prevent suppuration. Cases of the typhoid type should also be given serum in much larger amounts. Early diagnosis is very important so that serum may be given before the tenth day of disease if possible.

137

Drinker Respirator in Poliomyelitis

The treatment in the Drinker artificial respirator of forty-six patients with respiratory failure due to acute epidemic poliomyelitis is described in detail by M. B. BRAHDY and M. LENARSKY (*Amer. Journ. Dis. Child.*, October, 1933, p. 705), who consider that this procedure represents an outstanding advance in therapy. Cases of bulbar lesions were excluded after the first few weeks. It was frequently necessary to give repeated large doses of sedatives after the patient had been placed in the respirator. Constipation was often a troublesome complication, a contributing factor being the inability of the patient to produce a

positive intra-abdominal pressure. Orthopaedic treatment of the lower extremities and trunk was provided, although the apparatus prevented attention to the chest and arms. The youngest patient in the series was 14 months old and the oldest 24 years. The youngest patient to survive was aged 3 years. Those with paralysis of the diaphragm or intercostal muscles, or both, were classified as having spinal lesions. Of these there were thirty-four, and eighteen survived. The twelve bulbar cases, with involvement of the cranial nerves and presumed affection of the respiratory centre, proved fatal. The best indication of the progress of the disease was afforded by the temperature, the pulse rate and examination of the spinal fluid and blood counts giving no useful assistance in this respect. All except six of the patients who survived had temperatures under 101° F. after the third day. With recovery, weaning from the enforced artificial respiration was sometimes rather difficult. The authors emphasize the necessity of careful medical and nursing supervision, timely administration of sedatives, and parenteral injections of fluid, a time schedule for turning the patients on to their backs, and the prevention of any rise of the temperature of the air inside the respirator.

138 Ephedrine in Stokes-Adams Disease

C. S. HIGLEY and R. M. STECHER (*Amer. Heart Journ.*, October, 1933, p. 90) review a case of Stokes-Adams disease in which complete cessation of the attacks was brought about by the administration of ephedrine by the mouth. The patient was first treated with 10 minims of 1 in 1,000 adrenaline solution injected subcutaneously; this gave him relief for several hours. Barium chloride in 30 mg. doses was given three times a day for six days, but was discontinued, having been of no appreciable benefit. It was followed by 30 mg. of ephedrine sulphate by mouth. This afforded instant relief from the attacks, and in one week the individual dose was cut down to 20 mg. There were no more attacks, and after a fortnight the medication was stopped. The patient remained symptom-free for the next ten weeks, and was discharged. The attacks recurred, however, about a year subsequently; the symptoms were again relieved by ephedrine. Four years later, when the patient was aged 70, complete heart-block ensued, and improved for a time on ephedrine treatment, but he died five months afterwards. The authors report the post-mortem findings, and remark that according to Karsner, the most common cause of permanent A-V block is coronary disease with narrowing of the vessels supplying the junctional tissues. As the vessels narrow the A-V bundle and node undergo extensive degeneration and fibrosis. While the present patient showed marked arteriosclerosis of his peripheral vessels, both clinically and at necropsy, the coronary vessels were not seriously involved. There was no evidence of an aetiology relating to rheumatism, syphilis, diphtheria, scarlet fever, or toxic agents, and the authors are led to assume, therefore, that the coronary sclerosis was, nevertheless, sufficient to cause the clinical symptoms and the myocardial changes observed.

139 Avoidance of Embolus after Injection of Varicose Veins

F. REMENOVSKY (*Zentralbl. f. Chir.*, November 18th, 1933, p. 2719) alludes to Nobl's series of 20,000 injections of varicose veins with glucose solution without embolus, and to massed statistics giving 0.0024 per cent. mortality from that cause. He believes that in lethal cases the embolus arises in regions remote from the injection, as a result of inactive venous circulation. He pleads for ambulant treatment after the injections, even when local reaction is marked. If rest in bed is absolutely necessary from intercurrent cause, active and passive movements of the limbs should be carried out frequently, and the patient encouraged to sit up whenever possible. Recently a lethal embolus after varicose vein injection has been reported in Germany; the patient, coming to the clinic with her child, casually remarked that her leg was painful, and she had some local infiltration. She was kept in bed, with raised leg, for nine days—treatment which, Remenovskiy maintains, undoubtedly caused her death.

Ophthalmology

140

The Fundus Oculi in Diabetes

S. H. MCKEE (*Canadian Med. Assoc. Journ.*, November, 1933, p. 520), who has studied the ocular fundus in 1,272 cases of diabetes mellitus, points out that, because this disease occurs often in middle life, when arteriosclerosis generally manifests itself, a variety of conditions, such as retinal arteriosclerosis, vascular disorders, optic neuritis, and secondary glaucoma, may appear coincidentally without being necessarily originated by the diabetes. Cataract and retinitis are, he states, the most frequent lesions met with in diabetes, while retinal arteriosclerosis, disturbances of accommodation and refraction, iritis, chronic retrobulbar neuritis, amblyopia, and muscle disorders are not uncommon. The soft eyeball found in diabetic coma is pathognomonic, and differentiates this condition from insulin coma. One other similarly pathognomonic sign is the rare lipaemia retinalis, which involves both eyes. McKee believes that there is evidence of a direct causal relation between diabetes and retinitis. He agrees with Foster Moore that there is a clinical ophthalmic picture which strongly indicates a diabetic origin for an existing retinitis. This comprises solid and soapy, or waxy-looking, patches of retinal exudate with sharp-cut edges, distributed irregularly, and sometimes in a ring well wide of the macula; none of the soft-edged cotton-wool patches, frequent in renal cases; roughly circular haemorrhages in the deeper retinal layers; and no circular retinal pigment spots. The author strongly urges a fundus examination when there is any possibility of commencing arteriosclerosis in a case of diabetes in order that early discovery may lead to preventive measures against hypertension and cardiac and cerebral sequels.

141

The Retraction Syndrome

R. AEBLI (*Arch. of Ophthalmol.*, November, 1933, p. 602) summarizes the salient features of this syndrome as complete or partial absence of abduction, partial deficiency of adduction, retraction of the globe on adduction but rarely on abduction, an oblique movement up and in (or down and in) when adduction is attempted, narrowing of palpebral fissure on adduction and a tendency to widen on abduction, and paresis of convergence, the affected eye remaining in primary position. Anatomically there is a more or less complete substitution of fibrous for muscular tissue. The retraction of the globe may measure from 1 to 10 mm. Limitation of adduction is rarely complete, while abduction may be reinforced up and out and down and out by the oblique muscles. The narrowing of the palpebral fissure results from action of the orbicularis. Theories advanced to explain the syndrome include post-fixed tendon (or slip) of internal rectus, deficiency of check ligaments, lack of synergic relaxation of the external rectus, and, finally, action of superior and inferior rectus in the absence of any movement of the internal rectus. The oblique movement up or down on adduction may be due to pivoting on the optic nerve when in the retracted position, excessive spasmodic contraction of the inferior oblique, or abnormally high insertion of the internal rectus. The treatment is surgical, but occasionally the condition of the muscles is such that nothing can be done.

142

Diagnosis of Irido-ciliary Tuberculosis

H. LAGRANGE (*Brit. Journ. Ophthalmol.*, November, 1933, p. 679) states that uveal tuberculosis is a secondary condition, due to a blood stream infection demonstrable by animal injection. The wide clinical differences are due to variations in allergy. Proper diagnosis requires the unmasking of the primary focus, and Meller seeks pulmonary signs in every case, stressing the frequency of pleurisy. After examining the digestive tracts, bones, joints, and lymphatic system, the heart should be considered. The tuberculous heart is characterized by tachycardia, microcardia, and hypotension, and, in the absence of the last, tubercle may be excluded. Assistance may be obtained from tuberculin diagnosis, either by test treatment or by the homotopic technique of Marc Weiss,

the microleucocytic culture of Loewenstein, and the inoculation of aqueous into guinea-pig glands. The lesions of tuberculous iridocyclitis result from varying factors—those referable to the bacillus and those to the conditions of the local tissues. Tuberculous products may produce different reactions in different subjects, or at different periods of the disease in the same subject; hence the protean manifestations of the disease.

143 Chronic Inflammation of the Meibomian Glands

P. D. HENRIKSEN (*Norsk Mag. f. Laegevid.*, November, 1933, p. 1248) records a case of chronic inflammation of the Meibomian glands of seventeen years' duration in a woman aged 24 years. The conjunctivae showed several growths caused by a sticky, purulent fluid, which filled the glands and could be squeezed through the openings in the margins of the eyelids. A few fistulae leading from the growths to the conjunctiva were also present. The condition was found to be due to a Gram-negative encapsulated bacillus, grown in pure culture from the pus, and agglutinated and precipitated by the patient's serum.

Obstetrics and Gynaecology

144 Rectal Ergotamine Tartrate in the Puerperium

W. RECH and F. RÄBER (*Zentralbl. f. Gynäk.*, November 4th, 1933, p. 2594) quote Röthlin's finding, from experiments in cats, to the effect that ergotamine tartrate is absorbed readily after rectal injection in solution, but not at all from suppositories. Clinically, these authors found in a hundred cases in which lochial stasis, delayed uterine involution, or fetidity of the lochia called for treatment by ergot, that rectal injection of 1 mg. of ergotamine tartrate (gynergen) dissolved in 5 to 10 c.cm. of 5 per cent. dextrose solution was as effective as much larger doses given orally or intramuscularly. Comparing the incidence of puerperal morbidity (as judged by criteria of the type recorded above) in a hundred cases each of normal delivery in which rectal injections of ergotamine tartrate had or had not been given on the second, third, and fourth days of the puerperium, they found that the injections appeared to reduce the morbidity from 60 to 17 per cent. Of the treated cases only one had puerperal pyrexia above 37.9° C., as against eleven untreated cases having a temperature of 38° or over.

145 Nephritis and Pregnancy

J. R. GOODALL (*Amer. Journ. Obstet. and Gynecol.*, October, 1933, p. 556) quotes five cases which, though giving all the data of chronic nephritis, improved under pregnancy. He supports Hofbauer's teaching that both the so-called chronic nephritic and the pre-eclamptic types arise out of a secretory dysfunction which is often pluri-glandular, but in which the main factor is uncompensated overproduction of posterior pituitary hormone. The antidiuretic element from this gland is stated to be consistently demonstrable in the blood of nephropathic pregnant women. The pressor element is demonstrable only when the hormone is in very high excess, raising the blood pressure to 180. Normally these substances are rapidly eliminated post partum; if this relief fails eclampsia follows. A pituitary normal but with low reserve gives rise in pregnancy to low blood pressure, low uterine contractility, and low muscle nerve irritability—that is, hypopituitarism. A hyperactive gland further stimulated from the placenta gives rise to anti-diuresis and raised blood pressure with resulting albuminuria, nephritis, liver necrosis, and their accompanying symptoms. Water retention is a resultant of antidiuretic overaction plus the metabolic poisoning due to lowered elimination; hence, restoration of function follows removal of the placental stimulus. Excess of chloride excretion occurs along with anti-diuresis, with resulting acidosis, and also damage to the glycogenic function of the liver, with transient glycaemia and glycosuria, then enhanced waterlogging. Vagotonic action leading to anaemia of the brain accounts for eclamptic convulsions. Thus the chronic toxic and fulminating cases are traceable to the

balancing of under- or over-activity of the pituitary and other endocrine glands. The parallel with thyroid dyscrasias is perfect. Treatment, according to Goodall, must be the avoidance of emotion and the use of sedatives and eliminants; for severe cases starvation and water-free diet may be tried for three days, followed by chloride and carbohydrate-free diet. A blood pressure of over 180 warrants interruption of pregnancy, which is best performed on the third or fourth day of treatment in chronic cases.

Pathology

146 Virus Origin of Pemphigus and Dermatitis Herpetiformis

E. URBACH and S. WOLFRAM (*Med. Klinik*, November 24th, 1933, p. 1619) describe experiments in which they succeeded in producing symptoms of disease in rabbits inoculated with material from patients suffering from pemphigus and dermatitis herpetiformis. The material used was microscopically and culturally sterile. If only small amounts were available the subdural route was used for injection; with larger amounts the intravenous route was found most satisfactory. Vesicle fluid proved more potent than blood serum. The symptoms produced were either a paralysis of the extremities from which recovery sometimes took place, or a cachexia coming on several weeks after inoculation. Histologically the picture in both types was that of a disseminated encephalomyelitis. In four out of five cases of pemphigus and in seven out of eleven cases of dermatitis herpetiformis positive results were obtained in rabbits. Control experiments made with tissue fluids of normal persons on a total of sixteen animals proved negative. Passage experiments from the primarily infected rabbit to a second rabbit revealed the possibility of setting up a similar clinical and histological picture. In these experiments, fifteen out of twenty-four of which were successful, brain suspension proved the most virulent, but blood serum was found to be sometimes potent. Skin lesions were never observed. The authors conclude that pemphigus and dermatitis herpetiformis are probably virus diseases, the virus being dermatotropic in man and neurotropic in the rabbit.

147 Ultrafiltration of Blood

A rapid method for obtaining protein-free ultrafiltrates of blood and plasma is described by C. WILSON and E. R. HOLIDAY (*Biochem. Journ.*, vol. xxvii, No. 4, 1933, p. 1095). It is based on that suggested by Smith in the same periodical in 1928, but has been modified so as to improve the rate and yield of filtration, and to give membranes which are reliable as well as simple in preparation. The authors found alcohol-ether-acetic acid-collodion membranes ideal for rapid filtration, but too fragile to be used repeatedly. They have found a suitable one to be a glacial acetic-collodion membrane on a filter-paper basis, similar to the type described by Kreuger and Ritter in 1930. Membranes of 4 per cent. collodion can be used for several filtrations without deterioration of the surface. The rate of filtration under pressure of 70 cm. is slightly slower than with the alcohol-ether-acetic acid-collodion membranes. After filtration, the membrane surface is cleaned with 2 per cent. sodium bicarbonate solution, and the membrane is washed on the filter with 50 c.cm. of the same solution; followed by distilled water. It can then be preserved in distilled water until required for further use. The exact volume of collodion used for each membrane does not need to be standardized, since variations in the filtration rates do not seem to be induced by changes in thickness of the membranes. It is said to be possible to obtain 25 c.cnt. ultrafiltrate from 30 c.cm. plasma in thirty minutes. In certain injection experiments it was found to be possible to reduce the time from the taking of the blood from the vein to its injection into the animal to forty-five minutes. The filtration can be conducted under aseptic conditions at 0° C. There is thus little danger of loss of labile substances through decomposition.

FEB. 24, 1934]

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

148 Temperature of the Gastro-Intestinal Tract

J. S. HEPBURN *et al.* (*Arch. Int. Med.*, October, 1933, p. 693) have investigated the temperature of the gastro-intestinal tract and the influence on it of hot and cold foods and physical therapeutic agents. In both sexes the gastric temperature was usually higher than that of the mouth, the average difference being 0.9° F. in men and 1.25° in women. Great variations were found in the gastric temperature in short intervals of time. In men the temperature of the upper part of the intestine ranged between 98° and 100.1° F., with an average of 99.1° ; in women between 98° and 99.9° , with an average of 98.9° . The sigmoidal temperature was always higher than the oral one, on the average by 2.9° . Ingestion of iced water or ice-cream produced a marked decrease in the gastric temperature, followed by a rise, at first quite rapid, and then progressively slower. The average recovery time was more than half an hour. The use of the ice water in a test meal delayed the emptying time of the stomach from fifteen to thirty minutes. Leakage of a cold beverage through the pylorus seemed to lower the temperature of the upper part of the intestine by several degrees. The authors think that this may throw light upon the aetiology of gastro-enteric disturbances in patients who have a rapid gastric emptying time, and partake freely of cold beverages. The ingestion of hot coffee gave rise to a marked increase in gastric temperature, followed by a decrease which was rapid at first. No evidence was obtained that the application of heat or cold to the abdominal wall caused any change in the gastro-intestinal temperature, and the authors doubt the value of ice applied to the abdominal wall in gastric or intestinal haemorrhage, or of the local application of heat to promote healing in gastric or duodenal ulcers.

149 Diagnosis of Latent Cardiac Insufficiency

K. BARTH (*Munch. med. Woch.*, November 17th, 1933, p. 1817) considers it important, in order to avoid the possibility of over-straining the heart at critical times, to establish indications by which the practitioner can recognize the early stages of that process which leads to a diminished activity of the cardiovascular system. He states that although tests exist for the estimation of the function of the heart, control data from early periods are necessary to enable the proper interpretation of their significance in cases where the insufficiency is very latent. The history of the case is difficult to evaluate properly and the elimination of hysterical or neurasthenic reports requires special consideration. The author therefore gives a series of physical and mental symptoms which increase the likelihood of latent cardiac insufficiency. Of gastro-intestinal symptoms, gastric catarrh, flatulence, constipation, feeling of fullness, and diminution of appetite are considered important. Cervical muscular pain, tiredness, and dullness of the voice are sometimes the first signs. Headache, frontal pressure, general weakness and tiredness, unsteady gait, and sometimes vertigo on standing up or bending down may also be indications, while the presence of haemorrhoids, venous congestion, and pains in the back must be noted. Great stress is placed upon sleeplessness, and especially waking during the night. Such accessory signs as increased perspiration (day and night) and failure of potency are helpful indications. Latent cardiac insufficiency may also manifest itself by certain psychological changes—for example, irritability, depression, impatience, anxiety, phobias, forgetfulness, and often loss of determination and decision. It is considered that many people are unwarned of latent cardiac insufficiency until it is too late.

150

Chronic Barbitone Poisoning

J. RAVN (*Hospitalsidende*, November 9th, 1933, p. 1103) draws attention to the difficulty of detecting the ill effects of prolonged veronal medication. The earliest effects are neurasthenic symptoms, and it is often for just such symptoms that veronal is given in the first place. It is only in the comparatively late stages of chronic veronal poisoning that the patient suffers from weight, lassitude, anorexia, insomnia, convulsions, vomiting, cardiac symptoms, and haemorrhages from the gastro-intestinal tract. In the asylum to which the author is attached veronal is preferred to the other drugs in the same group because it is comparatively cheap and its action is prolonged to the following day. To ascertain if prolonged veronal medication injures the liver parenchyma, the author examined the urine of fifty patients for urobilinogen and bile acids. These patients had been given from 25 to 75 cg. of veronal daily for a minimum of six months and a maximum of five years. Urobilinogen was sought with Ehrlich's reagent and bile acids with Hay's test. As many as thirty-two gave a positive reaction to one or both of the substances looked for. Fifty other inmates of the asylum who had not been given veronal, and who in other respects were comparable with the first group of fifty patients, served as controls. Only sixteen of them gave a positive reaction in the urine to one or both of the substances sought. In no case were they present in large quantities in either group. The author is inclined to consider the high proportion of positive reactors in the veronal group as fairly convincing evidence of injury to the parenchyma of the liver from chronic veronal poisoning. The risks of such poisoning may be reduced by not giving this drug for more than eight to ten days in succession, or by supplementing it with morphine and scopolamine in order that the dosage of the veronal may be appreciably reduced.

151

Vaccination with B.C.G.

W. H. PARK, CAMILLE KERESZTURI, and LUCY MISHULOW (*Journ. Amer. Med. Assoc.*, November 18th, 1933, p. 1619) record the results they have obtained with B.C.G. vaccine in New York. Infants were selected in tuberculous families and either vaccinated orally with B.C.G. during the first ten days of life or kept under observation in a control group. The environmental conditions were fairly similar, though certain differences existed. For instance, the vaccinated infants were removed from their parents for one month after immunization, while the control infants were left at home. Again, the control group was rather more heavily exposed to tuberculous infection than the vaccinated group. Some of the infants were under observation for five years, but with most of them the observational period was shorter. Altogether three out of 239 vaccinated and seven out of 189 control infants died of tuberculosis. The non-tuberculous mortality, on the other hand, was considerably higher in the vaccinated than in the control group. Another series of children from tuberculous families was submitted to parenteral vaccination with B.C.G. These children were not vaccinated till some time after birth, but all reacted negatively to tuberculin. In the corresponding control group some children had a positive and some had a negative tuberculin reaction. During the observational period none of the 150 vaccinated children died of tuberculosis. Of the 155 control children with an initially positive Mantoux reaction, five died of tuberculosis, while of 269 control children with an initially negative reaction, four died of tuberculosis. The authors, while admitting that the differences are not significant, conclude that B.C.G. vaccination apparently gives some measure of protection against tuberculosis, and is worth performing on infants and children who have a negative Mantoux reaction and are to be exposed to infection.

Surgery

152 Dangers of Colloidal Thorium in Pyelography

In a case recorded by K. SCHEELÉ (*Zentralbl. f. Chir.*, October 21st, 1933, p. 2483), radiological and necropsy findings, forty days after retrograde pyelography in which colloidal thorium dioxide (thorotrast) had been used, showed retention of the medium in the renal pelvis and parenchyma, with occlusion of the urinary tubules; leucocytes and many casts had been present in the urine. In other cases precipitation of non-excreted thorotrast has led to false diagnosis of stone. Scheele has found traces of it in the kidneys six months, and Freymann two years, after pyelography. F. KRAUSS (*ibid.*, p. 2487) describes the case of a young female patient in whom pyelography after thorotrast injection was done for suspected hydronephrosis. Twelve months later symptoms were still present, but the urine, cystoscopic findings, and results of kidney function tests were normal. Radiography showed radial shadows in the kidney which, in reality remnants of thorium, were at first taken as evidence of calcification—a suggested diagnosis which considerably aggravated the functional symptoms.

153

Treatment of Scoliosis

J. CORNET (*Le Scalpel*, November 4th, 1933, p. 1134) describes a new method of treatment for scoliosis by means of a special plaster jacket which is applied between periods of treatment by gymnastics, breathing exercises, and massage. The patient is dressed in a cotton vest and is suspended in a Sayre's collar. The plaster jacket is then applied, taking support from the pelvis below, and completely surrounding the thorax. A rubber bladder is then placed over the costal prominence laterally and the plaster is finished off over this and is supported firmly on the shoulders. A large window is then cut in the left side of the jacket. As soon as the plaster is dry the bladder is inflated by a pump, causing pressure which pushes the left side of the chest through the aperture in the jacket. Each week the bladder is further inflated, and the patient is encouraged to breathe deeply inside the plaster. The action of the jacket is twofold. By the suspension of the patient the curvatures of the spine are corrected, whilst the inflated bladder presses the ribs towards the left and also assists in correcting the spinal curvature. The results of treatment by this method are satisfactory, and the amount of pressure is easily regulated, whilst the unimpeded respiratory movements further help to correct the deformity.

154

Cholecystectomy for Typhoid Carriers

P. BRAESTRUP (*Hospitaltidende*, November 16th, 1933, p. 1132) contributes a successful case of cholecystectomy for the typhoid carrier state—a woman, aged 27, whose faeces had continued to contain paratyphoid B from three to four months after infection. After the removal of the gall-bladder, which contained stones, pus, and paratyphoid B, the organism could not be demonstrated by any of the six subsequent examinations of the faeces. Reviewing the literature, Braestrup notes that operations on the gall-bladders of 131 carriers were collected in 1932 by Eichhof. To these he adds sixteen other cases, including his own, and brings the total up to 147. As many as 105 of these cases ceased to be carriers, while twenty-seven continued to be so, eight were inadequately followed up and examined, and seven had a fatal termination—in only two of the latter could death be directly traced to the operation. In the cases reviewed, the gall-bladder was almost invariably found at operation to contain stones or to show some other morbid condition, and the author notes it as curious that, in the few cases in which a normal gall-bladder was found, the operation had no effect on the carrier state. This finding confirms the attitude of those surgeons who prefer to operate on the carriers who present definite evidence of disease of the biliary system, and who are not inclined to take the risks of a 'cholecystectomy' when there are no signs or symptoms referable to the gall-bladder.

364 B

155

Eventual Results of Phrenicectomy

E. RIST and AUERBACH (*Bull. de l'Acad. de Méd.*, November 14th, 1933, p. 358) affirm that the ultimate results of phrenicectomy are not as favourable as the immediate effects might indicate. Of 200 cases in which this operation had been performed two and a half to ten years previously, 100 showed such marked improvement in six or eight months as to give hopes of cure; of these, however, only twenty-six were finally cured, and sixteen showed further improvement. Death has occurred in eighty-six of the 200 cases, and thirty-six are in poor health. Of the 100 patients, seventy-nine had received, after operation, sanatorium or semi-sanatorium treatment; of the twenty-six cures twenty-three and of the improved cases fifteen fall into these groups. The authors conclude, therefore, that phrenicectomy is more successful when followed by prolonged sanatorium treatment, this realizing the two essentials of methodical rest and permanent medical control. Hence, also, artificial pneumothorax is superior to phrenicectomy. In addition, the foregoing results demonstrate the great value of sanatorium therapy in the treatment of pulmonary tuberculosis.

Therapeutics

156

Duodenal Fluid in Pernicious Anaemia

W. KÜHNAU (*Münch. med. Woch.*, November 10th, 1933 p. 1772) states that administration of raw liver or live extract makes up for the deficiency of the anti-anaemic principle, which is absent in pernicious anaemia. Discussing the question as to whether this anti-anaemic principle is a product of hepatic metabolism or is merely stored in the liver, this author favours the latter explanation, which is, he believes, suggested by the characteristic gastro-intestinal symptoms—atrophic and inflammatory changes with abnormal bacterial proliferation. He thinks it probable that the anti-anaemic principle is elaborated in the gastric mucosa as a hormone from albumin-containing vitamin B₁₂, and that this is stored in the liver cells. Recent researches show that preparations of gastric mucosa are as efficacious as liver extract, and actually superior in gastric sclerosis. Pathological changes in the upper intestinal mucosa which accompany pernicious anaemia suggested that the healthy duodeno-jejunal mucosa might contain the anti-anaemic principle as well as the gastric mucosa, and consequently that normal duodenal fluid might supply the deficiency. Bile present constantly in duodenal fluid may carry anti-anaemic substances stored in the liver. Accordingly, Kühnau has treated four cases of severe pernicious anaemia by administration of fresh duodenal fluid obtained from healthy persons. After five administrations rapid increase of reticulocytes occurred. One patient declined further treatment and died shortly afterwards. The others improved greatly. One patient who had degenerative changes in the spinal cord recovered sufficiently to walk considerable distances on level ground without a stick. Two patients look well and have resumed work.

157

Passive Immunization in Poliomyelitis

K. WALTNER (*Orvosi Hetilap*, December 16th, 1933, p. 1137) reports on a major poliomyelitis epidemic in the summer of 1932 in the Hungarian town of Szeged, and on the results obtained by specific protective immunization. Of 7,000 children aged up to 5 years, 790 (11.3 per cent.) received injections of 10 to 20 c.cm. of adult whole blood. The morbidity rate per 1,000 head was 5.1 for children thus protected and 10.9 for children not protected. For the ages 5 to 11 the figures were as follows. Number of children, 15,300; of these, 1,050 were protected—that is, 6.9 per cent. Morbidity rate per 1,000 head: protected children, 3.8; non-protected children, 6.2. For the ages 11 to 14: number of children, 18,000; protected 1,100—that is, 6.1 per cent. Morbidity rate per 1,000 head: protected children, 3.6; non-protected, 5.4.

The majority of the protected children received only one injection. Of the six cases in which protected children fell ill, five were cured, the cerebro-spinal fluid returning to normal after a period ranging from six to ten days. In four cases no paralytic symptoms whatever were observed; the fifth showed only a lack of the patellar reflex on the left side from the fourth to the ninth day of illness. The material used was adult whole blood. The mortality rate of the total number of affected children was 8.8 per cent. for hospital cases and 24.1 per cent. for home cases. Waltner concludes that, although the number of cases was too small to serve as statistical proof of the efficacy of blood prophylaxis as applied to poliomyelitis, it is, so long as no more efficacious method is evolved, the duty of the medical profession to apply prophylactic injections of adult blood in every case that comes under their notice.

158 Malarial Treatment of Chronic Gonorrhoea

P. BERGGREEN (*Derm. Woch.*, November 11th, 1933, p. 1603) describes five years' experience in malarial treatment of 233 cases of chronic gonorrhoea (in both sexes), many of which had proved refractory to vaccine injections of living gonococci. In 90 per cent. of women and 85 per cent. of men, after an artificial infection with malaria, it was not possible, in spite of provocation, to demonstrate the gonococcus after the last rigor. The average duration of treatment was fifty-five days in women and thirty-six days in men. The treatment had to be suspended in six patients, but two instances only of actual ill effect were noted—pancarditis and activation of pulmonary tuberculosis respectively. Pre-existing gonococcal complications were improved or unaffected during treatment. The average reduction in blood haemoglobin during treatment was 20 per cent., and a careful general medical examination preceded the treatment in every case.

159 Treatment of Arteritis Obliterans

J. L. LOMBA (*Paris Méd.*, November 25th, 1933, p. 425) records a case of gangrene of a toe of the right foot, associated with fainting attacks and acute melancholia. Dietary and insulin therapy produced only a temporary remission, but cure of both mental and arterial conditions was obtained in three and a half months by intravenous injections of hypertonic saline serum. Affirming his belief that chronic arteritis obliterans, of both senile and juvenile types, is a general, as opposed to a purely local, malady of the arterial system, Lomba states that as the pathogeny is yet unknown (infection and endocrine disturbance are theories advanced), treatment can only be symptomatic. Special dieting is inefficacious, though essential in hyperglycaemic cases. Cold and damp must be avoided and the use of tobacco prohibited. Useful physical agents are the passive mechanical treatment of Buerger, thermotherapy and hydrotherapy, diathermy (especially in juvenile cases), ultra-violet and infra-red rays, and radiotherapy. Of chemical agents, intravenous injections of sodium citrate (in senile forms) and of hypertonic saline serum and subcutaneous injections of acetylcholine are of value. Of biological remedies, insulin and the circulatory hormone of Frey have given good results; injections of muscle and ovarian extract and of female blood have also been recommended. Protein therapy with T.A.B. vaccine may be beneficial. Lomba believes that surgical procedures (periarterial sympathectomy, ligation of the veins, unilateral suprarenalectomy, lumbar or lumbo-sacral ganglio-sympathectomy and amputation) should be resorted to only when medical measures fail.

160 Intravenous Morphine in the Relief of Pain

H. IACOBÆUS (*Nord. Med. Tidsskrift*, November 4th, 1933, p. 1321) contrasts the frequent futility of subcutaneous injections of morphine for incurable cancer with the invariable reliability of intravenous injections. He hints at the possibility of the subcutaneous tissues of the dying sometimes failing to absorb certain drugs. In Denmark the preparation commonly employed for subcutaneous injection contains glycerin, which is apt to destroy the red

blood cells. The author recommends for intravenous injection a 5 per cent. solution of the citrate of morphine, which can be kept sterile if a little benzoic acid is added. It is easy to understand why the effect of an intravenous injection should be more rapid and powerful than that of a subcutaneous injection, but what is surprising is the longer duration of the effects of the former.

Dermatology

161

Ringworm of Hands and Feet

E. D. OSBORNE, E. D. PUTMAN, and R. J. RICKLOFF (*New York State Journ. Med.*, November 1st, 1933, p. 1270) recommend the wide use in public baths of a 1 per cent. solution of sodium hypochlorite as a cheap, harmless, and effective prophylactic against ringworm of the feet. The pans of this solution, through which the bathers should be obliged to walk, have to be replenished on alternate days. This procedure proved very satisfactory in schools where it was tried over a period of three years. As regards treatment, the authors favour one hypo-erythema dose of x rays in acute cases of ringworm of the hands and feet rather than the repeated fractional dose method. They add that if four or five fractional doses do not produce a result in chronic cases the treatment should be stopped. Trichophytin yielded disappointing results in a hundred chronic relapsing cases. It is stated that effective treatment of such ringworm cases demands recognition of the part played by allergy and the development of dermatophytids; clinical differentiation from dermatitis venenata; the employment of laboratory investigations; an understanding of the aetiological influences of soil, heat, and moisture of the hands and feet; and an appreciation of any systemic disturbance influencing the sweat secretion. In the acute vesiculo-pustular stage the authors commend the use of wet dressings for twelve to fourteen hours a day, either of metaphen in a 1 in 2,500 to a 1 in 5,000 dilution, or of aluminium subacetate in a 1 in 16 dilution. For the remaining eight to ten hours they employ plain boric ointment, a 2 per cent. sulphur precipitate ointment, or a soothing astringent dusting powder containing 1 per cent. menthol, 5 per cent. chlorotone, 5 to 10 per cent. tannic acid, and 30 per cent. boric acid. Rest in bed, with elevation of the affected limbs, is helpful, and x-ray exposures have special value in this type of case.

162 Occult Venereal Lymphogranuloma (Nicolas and Favre's Disease)

BEJARANO and GALLEGO CALATAYUD (*Crónica Médica*, October 15th, 1933, p. 721), emphasizing the preponderance of this disease in males—95 per cent. of all cases in their practice and in that of Campos Martín—postulate that the lymphatic system of females is much more resistant to infection than that of males, and cite the analogous experience of Ivanyi and Neumann, who in 3,239 cases of soft chancre in both sexes found 2,728 inguinal buboes, of which but 511 were in females. The present authors state that in the three summer months of 1932 a great increase in the incidence of lymphogranuloma in the male was noticed in the Red Cross centre in Barcelona. Inquiry at the various V.D. clinics and among practitioners failed to discover the source of this epidemic. Campos Martín and Calatayud tested forty prostitutes, certified to be healthy, with Frei's intradermic reagent, carefully controlled. A positive response in 15 per cent. of the subjects was the result, though none presented the faintest indication of the disease. De Gregorio of Zaragoza and Nicolau and Banciu of Bucarest had a similar experience. The writers then tested seventy-five prostitutes, certified to be in excellent health and without signs of the infection. Careful control tests were done. Of these seventy-five, only forty-nine were seen again by the writers, and of these, 11 per cent. proved to be strongly positive. They were drawn from the very lowest class of prostitute, their "sisters," plying their trade in more expensive

markets, invariably giving a negative reaction. None of these women had at any time shown a trace of venereal lymphogranuloma; and the question of the origin of the small epidemic remained unsolved until a soldier was found affected by the disease in the military hospital of Barcelona. This man had left his native village but a few months before, and had had no sexual adventures until his arrival in Barcelona, where his experiences were confined to coitus on a few occasions with one public woman. A careful examination of his paramour yielded neither history nor sign of venereal disease, but she reacted in the most convincing manner to Frei's test.

163 Treatment of Suspected Syphilitic Lesions

A. MUSGER (*Derm. Woch.*, October 28th, 1933, p. 1532) discusses the duty of the physician in treating a sore in which, though slightly or strongly suggestive of a primary syphilitic lesion, examination for the spirochaete has been negative. Oppenheim, who has reported fourteen cases, later proved to be syphilitic, in which the chance of early abortive treatment was missed, owing to repeatedly negative examination for spirochaetes, has advocated anti-syphilitic medication (irrespective of microscopical findings) for every clinically suspicious genital erosion or ulcer. Musger reports a series of 120 genital sores clinically diagnosed as erosive balanitis, herpes, erosion, inflammatory phimosis with gland swelling, or ulcus molle, but fraught with a suspicion of primary sore and preceded by a suspicious coitus; twelve weeks or a longer control was possible. In all but two no clinical, serological, or microscopical evidence of syphilis was afterwards obtainable. In the remaining two the spirochaete was found subsequently, but in the sero-negative stage. It is concluded, that anti-syphilitic treatment is unjustified if the sore, repeatedly and frequently examined, has not yielded spirochaetes.

Obstetrics and Gynaecology

164 Dangers of Intrauterine Pessaries

A. SJÖVALL (*Zentralbl. f. Gynäk.*, November 4th, 1933, p. 2598) cites from the literature: (1) thirteen cases of death following within one to five days after insertion of a contraceptive uterine pessary; (2) some 120 cases of septic abortion, of which a good number were lethal, following introduction of the pessary in the pregnant or (at first) non-pregnant uterus. The author states that if pregnancy should follow the intervention, abortion during the early months usually follows; nevertheless, not a few cases have been reported in which both the contraceptive pessary and the foetus have been delivered at or near term, the latter sometimes showing marks of injury by the former. In a case of Sjövall's, spontaneous delivery at term of a normal child was closely preceded by expression of a silver intrauterine pessary which the patient herself had introduced two years previously with the aid of an illuminated speculum and removed during the menses.

165 Treatment of Uterine Cancer

H. H. SCHLINK and C. L. CHAPMAN (*Med. Journ. of Australia*, October 7th, 1933, p. 476), who give a good review of the results of treatment of this disease, urge the abandonment of the classical subtotal hysterectomy and the substitution of the total operation, or, preferably, the safer and less difficult subtotal procedure, with enucleation of the endocervix. They think that radium should occupy the same place in operative treatment in cancer as does salvarsan to mercury and iodides in syphilis. Radium acts quickly, kills the local lesion or renders it inert, and thus affords time for operative measures to be undertaken in a clean field. The uterus should always be removed after radium therapy. The authors state that radium had no effect on cancer deposits in the lymph glands, which were secondarily affected in 10 per cent. of their operated cases. They obtained the best results with a dosage of 4,000 to 5,000 milligram-hours with a

1 mm. platinum filter, and consider a dosage of 2,000 milligram-hours inadequate to eradicate even a localized growth. Vaginal dosage should never exceed 2,000 milligram-hours for fear of subsequent injury to the bladder or rectum. The most satisfactory sequels were those after irradiation of the whole uterine cavity. In some cases the authors prefer needles to vaginal corks or plaques (lead boxes), because the first are less easily displaced. The best time to operate is regarded as three to four weeks after the exposure. It is added that diathermy has been abandoned because of the frequency of subsequent rectal, vesical, and peritoneal fistula formation. Radium treatment is held to be contraindicated in very advanced cases; in such it is better to eurette away the necrosing tissue, and to apply zinc chloride or acetone.

Pathology

166 Alkaline Therapy and Gastric Secretion

Z. STARY and P. MAHLER (*Med. Klinik*, November 3rd, 1933, p. 1509) report the following findings from giving before or with a test meal in the fasting state sodium bicarbonate, calcium carbonate, or magnesium oxide. The amount of gastric secretion was diminished to the greatest extent by the first, rather less by the second, much less by the third: the reduction was greater when the powder was given with, not before, the meal. Chloride concentration was diminished initially after soda, increased slightly after chalk, and affected inconstantly by magnesium, but the total effective chloride secretion was lowered in each case, in correspondence with the less amount of juice. Free hydrochloric acid reappeared soonest after soda, much later after the other two drugs. Mechanically, soda adhered less closely to the mucosa than the other preparations.

167 The Blood in Whooping-cough

D. MORITZ and L. LACKNER (*Arch. de Méd. des Enf.*, November, 1933, p. 669) made a study of the blood in sixty-five cases of whooping-cough, the ages of the patients ranging from 2½ months to 15 years. In forty-five the disease was uncomplicated, while in twenty, one or more complications occurred. The results were as follows: (1) the haematology of whooping-cough is characterized by lymphocytosis with an absolute or relative retardation of the sedimentation rate; (2) a number of lymphocytes exceeding 10,000 with an absolute or relative retardation of the sedimentation rate is in favour of the diagnosis of whooping-cough, but the absence of these changes does not exclude it; (3) the complications of whooping-cough produce a moderate shift to the left in the leucocyte picture and the sedimentation rate is accelerated; (4) examination of the blood enables the diagnosis of whooping-cough to be made at an early stage or in atypical forms of the disease.

168 Creatine Excretion as a Test of Muscular Impotence

As it has been proved that men of athletic build, after ingestion of large quantities of creatine, eliminate only traces, while in women and children the urinary elimination—never total—continues for many days, W. L. DULIERE and J. CORNET (*Bruxelles-Médical*, November 5th, 1933, p. 29) judge that the rapidity with which a quantity of ingested creatine is eliminated by the kidneys is a test of muscular impotence. If in the twenty-four hours following the ingestion of 3 grams (an adult dose) of this salt at least 2 grams are eliminated, and especially if the residual gram is eliminated the following day, the muscular system may be considered as functionally insufficient. An illustrative case of muscular weakness and degeneration is described, in which this test proved of correct value; short notes on the chemical tests for creatine are also given. The authors mention the diuretic action of this salt; after ingestion of 3 grams the daily urinary volume is frequently doubled.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

169 Incidence and Importance of Threadworms

H. HELLSTEN (*Nord. Med. Tidskrift*, November 11th, 1933, p. 1358) has examined 410 persons in Sweden for threadworms. A piece of lint impregnated with vaseline was introduced into the rectum on the index or little finger in a rubber finger-stall. After palpation of the rectum immediately above the sphincter, the lint was withdrawn and washed out in water and ether. An examination was then made for oxyuris eggs after centrifugalization. Among the 410 persons thus examined were 310 hospital patients, sixty inmates of an asylum, and forty school children. As many as 260 of the 310 hospital patients were under the age of 15. The frequency of infestation increased steadily with age. None of the sixty infants examined harboured the threadworm and there were only two who did so out of the forty children between the ages of 1 and 2. Between 2 and 4 years the incidence was 25 per cent.; between 4 and 7, 47.5 per cent.; between 7 and 10, 52.5 per cent.; and between 10 and 15, 58.75 per cent. The incidence of infestation for all the age groups from 0 to 15 was 30.3 per cent. As many as forty-two of the sixty asylum inmates harboured the threadworm. This high incidence of 70 per cent. was presumably due to defective hygiene. Twenty-seven of the forty school children harboured threadworms. The author's review of the opinions expressed as to the harm done to its host by the threadworm and as to the indications for combating it shows little unanimity and still less knowledge of this subject at the present time.

170 Alkali Retention in Essential Hypertension

W. SCHARPFF (*Munch. med. Woch.*, November 3rd, 1933, p. 1739) alludes to recent findings of increased alkali retention in vascular hypertension, peptic ulcer, asthma, and other disorders in the aetiology of which vaso-neurotic factors have been thought to be important. In forty patients, of the average age of 58, in whom raised blood pressure was the only morbid objective sign to be detected, he found that alkali retention, as shown by measurements of the urinary pH before and after intravenous injection of sodium bicarbonate, was very different—extremes of 0.8 and 2 (difference in acidity) being noted. Correlating the findings with clinical data, he noted that treatment was effective in patients with little alkali retention; others did not respond.

171 Primary Cancer of the Lung

R. OVERHOLT (*Amer. Journ. Surg.*, November, 1933, p. 181) points out the discouraging results obtained by irradiation in the treatment of carcinoma of the lung, and considers that at present surgical extirpation of the lesion is the most hopeful method of obtaining a permanent cure. Earlier and more frequent use of x rays may render diagnosis possible whilst the disease is still localized in one of the pulmonary bodies and thus make surgical removal more successful and less dangerous. Bronchoscopy is also of value in diagnosis. Symptoms are determined by the position of the growth, which may be so situated that no apparent disturbance results. If the lesion is growing well out from the hilum it may assume a large size before any symptoms are noticed. A lesion in one of the larger bronchi will initiate a cough reflex, whilst partial obstruction of one of these bronchi may cause a wheezing respiration. If the mucosa of the bronchus becomes eroded haemoptysis is a common symptom. Chest pain is frequently present when the lesion is centrally located or of the hilar type. Intercoastal neuritis may be caused by infiltration in the mediastinum, or by

a peripherally located lesion with pleural involvement. A case is reported in which the patient, a man of 59 years, suffered from chest pain without cough or haemoptysis and had a large lesion at the right base in a posterior position. A diagnosis of a mediastinal tumour was made, but operation disclosed a primary bronchiogenic carcinoma with extension into the mediastinum. Complete removal being impossible, the right lower lobe together with the shell of the tumour was removed, and the patient had an uneventful convalescence followed by deep x-ray treatment. He died suddenly at the end of ten months.

172 Gas Gangrene following Therapeutic Injections

A. PERNYÉSZ (*Orvosi Hetilap*, November 4th, 1933, p. 175) records a case of bronchial asthma in which death from gas gangrene resulted twenty-one hours after the injection of 3 c.cm. of camphor oil and 3 c.cm. of cardiazol into the right upper arm; syringe and needles had been boiled for five minutes before use, and though the ampoules could not be examined the contents of others from the same box were found to be sterile. The author states that similar cases observed by him were mainly found in exhausted and febrile patients, while two-thirds of those described in the literature occurred in the course of pneumonia, the rest being found associated with asthma, typhoid fever, malaria, and surgical conditions. Generally the drug used was caffeine, though gas gangrene had also occurred following the injection of many other substances, including normal saline. The site of injection was usually the front of the thigh, but sometimes the puncture had been made in the arm, gluteal region, and abdomen. Cases had been reported by Gross-Fric, Kruse, and Junghans. The cause of the infection could not be traced with certainty. It is important, states Pernyész, to clean every ampoule with alcohol before use owing to the danger of the negative pressure drawing glass splinters inside when the neck is broken. In all cases the skin should be cleaned with benzene and tincture of iodine, the surgeon's hands should be clean, and needles and syringe should be boiled before and after use.

Surgery

173 Statistics of Cancer of the Colon

N. PAUS (*Tidsskr. f. d. Norske Lægefor.*, November 1st, 1933, p. 1143) has made a collective study, clinical or post mortem, of the cases of cancer of the colon observed in several Norwegian hospitals. It was the cause of death in 206 out of 23,356 cases coming to necropsy (0.9 per cent.). The disease was as common in men as in women, and rare under the age of 50. Of the cases coming to necropsy, 73.8 per cent. showed definite strictures of the intestines, and in 19.9 per cent. death was due to acute intestinal obstruction. A classification of the cases according as entero-anastomosis was performed early or late showed that the mortality was 20 per cent. for the patients not suffering from intestinal obstruction, whereas it was 35.9 per cent. for those with chronic intestinal obstruction and 76.5 for those whose intestinal obstruction was acute. In five cases the first sign of the disease was acute intestinal obstruction—a fortunate incident which brought the patient to operation earlier than usual. Of 571 patients operated on, 9.5 per cent. underwent an exploratory laparotomy only; 22.2 per cent. were provided with an artificial anus, 16.8 per cent. with an intestinal anastomosis, while on 51.5 per cent. a radical operation was performed. For this last, the operation mortality was 29.8 per cent. when the operation was performed in a single stage, and 15.7 per cent. when it

was performed in more than one stage. Of those who survived a radical operation, 75.3 per cent. were alive two years later and 30.7 per cent. ten years later. Paus concludes that secondary deposits occur comparatively late in the disease, and that the ultimate prognosis is good if a radical operation is performed early enough. The prognosis depends on the general practitioner: were he to secure an expert x-ray examination at once in every suspicious case, the mortality from this disease would, Paus believes, come down with a run. In only 22.4 per cent. of the author's material had a reliable x-ray examination been made.

174 Rupture of the Liver

M. BACHY (*Bull. et Mém. Soc. Nat. de Chir.*, November 25th, 1933, p. 1367) reports eight cases of rupture of the liver. In every case the rupture was due to trauma, and the patients had characteristic symptoms of severe intraperitoneal haemorrhage, pallor, quick pulse, and contraction of the abdominal wall with sharp pain at the point of injury. Operative treatment was carried out as soon as possible, the method of choice being suture of injuries in the liver by means of thick catgut on a large needle, care being taken not to damage the parenchyma of the liver. The subhepatic space was drained in every case. Prognosis depends on the severity of the injury—when there are many bleeding wounds in the liver the outlook is grave owing to severe haemorrhage. There may also be associated lesions such as haemothorax, injury to the diaphragm, pleuro-pulmonary complications, or rupture of the lower lobe of the lung, which add greatly to the severity of the condition. Of the eight cases reported three died, but the remainder recovered after operative treatment.

175 Sympathectomy and Vagus Resection in Asthma

R. GÖBELL (*Zentralbl. f. Chir.*, November 11th, 1933, p. 2662) describes a series of 110 bilateral sympathectomies, with 5 per cent. mortality; this has diminished since ether anaesthesia has been abandoned, and the operation is now done, if possible, in two sittings, separated by fourteen days' interval, in local anaesthesia. Recently avertin has also been used. Operations done for asthma numbered ninety-eight. Unilateral sympathectomy or right vagus resection (eight cases) showed transitory—usually no—improvement. Of twenty bilateral sympathectomies eight were cured and two improved. Bilateral operation on vagus and sympathetic was done in sixty-two cases; twenty-six were cured, eleven improved, and fourteen not improved; the remainder died or could not be traced. Göbell no longer tries the operation in patients aged more than 60, in whom he finds emphysema and bronchitis so firmly established that cure is impossible. He describes fully his technique for removal of the cervical sympathetic ganglia from the neighbourhood of the vertebral artery.

Therapeutics

176 Nucleic Acid Derivatives in Agranulocytosis

W. DAMESHEK (*New England Journ. Med.*, November 23rd, 1933, p. 1054) records a group of three cases of cyclic or relapsing agranulocytosis which were treated successfully with nucleic acid derivatives. He emphasizes the recurrent tendency in this condition, the almost specific response to treatment on these lines, the reactions following the use of pentnucleotide, and the haematological response (with special reference to the histiomonocytosis which occurs during recovery). He concludes that the relatively simple nucleic acid derivative, adenine sulphate, and the more complex mixture of pentose nucleotides are both highly effective and probably specific in the treatment of true agranulocytosis. He thinks that the adenine sulphate may represent the active principle

in the mixture of pentose nucleotides. It is thought probable that the response to intravenous injections of adenine sulphate is more rapid than that of pentose nucleotides given intramuscularly, and that it is to be noted under five days after the commencement of treatment. These derivatives of nucleic acid have apparently a specific action on the formation of bone marrow granulocytes, and thus attack what is probably the essential cause of the disease. Failures which have been reported are probably due to the use of the drug in conditions of leucopenia which were not primary in type but were secondary to severe sepsis, aplastic anaemia, or aleukemic leukaemia. In one of Dameshek's three cases there was striking improvement in the blood within eight hours after starting treatment, followed by definite clinical amelioration and subsidence of the bronchopneumonia in seventy-two hours. In another case the haematological reaction was noted in seventy-two hours, clinical improvement following after a little further time.

177 Artificial Pyrexia in Trigeminal Neuralgia

T. BÖCKHELER (*Münch. med. Woch.*, November 3rd, 1933, p. 1740), who saw a case in which sciatica, refractory to other treatments, disappeared during an intercurrent attack of erysipelas, has had favourable results from induction of artificial pyrexia in seven cases of trigeminal and three of occipital neuralgia. Recurrences, successfully treated on similar lines, were noted in some cases, but three to twenty-four months' freedom from pain was the usual result. Moewe has seen cure follow pyrexial treatment in a case in which injection of the nerve and Gasserian ganglion had been ineffective. The medium used was "pyrifer," a protein substance derived from non-pathogenic coliform bacilli, given intravenously in small doses, which were followed by preliminary intensification of the neuralgia; occasional fatalities, not necessarily attributable to its action, have followed its use in general paresis, but in the present series, from which old and debilitated subjects were excluded, no inconvenient results were noted.

178 Diphtheria Toxoid Prophylaxis

A. L. MCKAY (*Canadian Pub. Health Journ.*, November, 1933, p. 518) has been for the last eight years employing in Ontario diphtheria toxoid (anatoxine Ramon), and cites statistics in support of his contention that this preparation is a safe and effective agent in the prevention of diphtheria. He estimates that about 15 per cent. of the population has now been thus treated, and the provincial morbidity and mortality rates for this infection show a very marked and continuing fall since 1929, as compared with certain cities where no toxoid prophylaxis was attempted. McKay concludes that now a community can almost eradicate diphtheria by the administration of toxoid to a significant percentage (30) of its child population, particular attention being paid to the age group under 5 years.

179 Influenza and Sterility

A. L. WOLBARST (*Med. Journ. and Record*, November 1st, 1933, p. 293) suggests that influenza may be a possible cause of sterility on the following grounds. Stenosis of the vas deferens may occur as the result of infection when the organs at both extremities of it are apparently normal. Organisms similar to those found in focal influenza infections of the prostate, seminal vesicles, and epididymes can be recovered from the secretion occasionally found in the vas deferens. Influenza infection of the vas may occur and produce stenosis and permanent sterility unless relieved by vasotomy. In cases of azoospermia without obvious cause an inquiry should be made as to a previous infection with influenza, and if such a history can be obtained vasotomy should be performed as the only known means of restoring fertility. The author states that the stenosis in the vas was removed and motile spermatozoa restored to the semen in 45 per cent. of the cases treated by him.

Laryngology and Otology

180 Chronic Paranasal Sinus Infection

According to R. A. KERN and H. P. SCHENK (*Arch. of Otolaryngol.*, October, 1933, p. 425) chronic diseases of the lower respiratory tract that are attended by purulent sputum in large amounts are in most cases associated with chronic sinus infection, bronchiectasis being outstanding in this respect. Whether the sinus infection is primary or secondary is uncertain, but it is clear that attempts to cure such respiratory tract infections are doomed to failure until the sinus condition has been thoroughly treated. Significant points in this group of cases are the constancy of marked clouding of the sinuses on x-ray examination and on transillumination, and the usual finding of a red congested nasal mucosa. Acute sinusitis may lead to a subacute bronchial infection. The patients, usually young adults, suffer from a severe cold in the head, followed by cough, fever, and malaise for a few days. The symptoms ameliorate but do not cease, the cough, purulent sputum, and evening pyrexia persisting. Examination of the sinus often discloses an acute local infection without significant symptoms, but, on treating this effectively, all the symptoms disappear. Chronic inflammation of the sinus mucosa is often found in cases of seasonal hay fever or pollen asthma. Patients with perennial nasal and bronchial hypersensitiveness show a very high incidence of abnormality of the sinuses, both clinically and in radiographs. Whether primary or secondary in occurrence the sinusitis renders the nasal mucosa more sensitive to old allergens, may pave the way for sensitization to new inhalants or bacteria, and perpetuates the bronchial infection. Avoidance of the extraneous substances to which the patient is sensitive is often followed by a complete or partial subsidence of the mucosal swelling and the clearing up of the sinus infection. Only when this measure has failed is an operation on the sinuses indicated.

181 Blood Infection from Otitis Media

E. J. G. GLASS (*Journ. Laryngol. and Otol.*, November, 1933, p. 754) records an analysis of sixty-three consecutive cases of blood infection from otitis media which occurred in Nottingham between 1926 and 1932. It was found that the mortality rate was low in children under the age of 10, in cases of otitis media submitted to operation during the first week, in cases developing metastatic abscesses, and in haemolytic streptococcal infections treated with anti-scarlet-fever serum. The prognosis proved to be bad in patients over the age of 40, in chronic suppurative otitis media with acute exacerbation, when septicaemia had developed before the operation was performed, and in cases showing subcutaneous haemorrhage or jaundice. Of the sixty-three patients death occurred in thirty-five, the commonest terminal cause being such conditions as septicaemia and pyaemia. One recovered apparently from a septicaemic state, only to die from meningitis three weeks later. The blood culture in this case contained a non-haemolytic streptococcus.

182 Autohaemotherapy in Ozaena

M. DO SOUTO (*Rev. de Laryngol., d'Otol. et de Rhinol.*, November, 1933, p. 1171) advises autohaemotherapy in ozaena. He adopted this method owing to the results following its use in many dermatoses and to those obtained by peptone therapy in ozaena. Haemoclastic crisis with leucopenia and fall of arterial tension, an antitoxic and anti-infectious effect producing a stimulation and modification of blood reactions, and desensibilizing anticolloidoclastic effects have all been attributed to autohaemotherapy. The technique in ozaena is extremely simple: with a short-bevelled needle of calibre suitable to the size of the veins 5 to 10 c.cm. of blood are withdrawn from the vein at the bend of the elbow, and immediately injected, with the same needle without the addition of any solution (citrate, etc.), deeply into the

middle of the deltoid region. The initial dose for children is 3 c.cm. and for adults 5 c.cm. every two days. Larger doses than 5 c.cm. for children and 10 c.cm. for adults are never necessary. Though the number of injections is not limited, twelve per series suffice usually. After an interval a second series may be given if necessary. Appreciable effects are not evident before the fifth or sixth injection; after which improvement is astonishingly rapid. The only after-effects are a transitory slightly painful erythema at the injection site and a slight temperature. The treatment is contraindicated in cachectic and cardiac cases and in those with advanced arteriosclerosis, who tolerate protein shock badly. Do Souto does not claim cure by this procedure—cure signifies complete restitution of the bones and mucosa—but merely that it causes disappearance of the crusts and offensive odour.

183 Treatment of Acquired Deafness

J. B. PRAGER (*Med. Journ. and Record*, November 15th, 1933, p. 375) describes a three-stage method of treatment for acquired deafness which comprises diathermy, nebulization, and sound vibratory massage. Through pure aluminium electrodes a current starting with 100 milliamperes is passed, and is gradually increased until there is a comfortable sensation of warmth in the patient's ears. This is continued for half an hour, and it is argued that the circulatory changes so induced should be of considerable benefit. The patient should be allowed to remain in the chair for at least five minutes after the current has been turned off in order to obviate any feeling of dizziness or vertigo. The nebulization treatment follows. It consists of the introduction into the posterior nares of an oil containing camphor, menthol, and eucalyptus. The patient is finally seated in a comfortable chair before a machine which amplifies sounds transmitted to it by a phonograph record. The volume of these sounds is regulated by a control knob, and is increased until the patient feels a distinct vibration of both drum membranes. This is maintained for from three to eight minutes, the duration being determined by the condition of the patient. Prager states that the advantage of this form of aural sound massage lies in the fact that the amplitude of the sound waves is completely adaptable to the individual condition of the ears in each case. The physiological stimulus causes an active hyperaemia, which is evidenced by a blushing to be observed about the handle of the malleus and the drum membrane, and by a comfortable sensation of warmth. Repetition of the treatment results in improvement of nutrition; adhesions become loosened and disappear. The hearing gets better, tinnitus being abolished or relieved. Care must be taken to deal with any psychological factors present.

Obstetrics and Gynaecology

184

Chronic Mastitis

HOWARD C. TAYLOR (*Surg., Gynecol. and Obstet.*, November, 1933, p. 627) discusses the aetiology and treatment of 102 cases of non-malignant painful breast other than the circumscribed forms of chronic mastitis. Eighty of the cases were aged from 20 to 40. Characteristics are pain, generally bilateral, occurring before, and relieved by, the menstrual flow. An intermittent lump or secretion was found occasionally, and once bleeding. Pathologically the condition is probably only an exaggeration of normal menstrual variations. Relationship to cancerous growth was very doubtful, but that to simple neoplasms was marked. As aetiological factors other workers quote prolonged trauma (for example, in unsupported or compressed breasts), incisions for puerperal abscess, nervous instability associated with tachycardia or dysmenorrhoea, suggestion, ovarian disease, and any pelvic lesion. In the series under analysis sixty-six out of 102 were traceable to some special incident as puberty, marriage,

trauma, or pelvic operation, and thirty had followed the onset of dysmenorrhoea. Some menstrual abnormality was present in sixty-eight. Lactation was apt to be deficient. Low fertility in fifty-five cases resulted from the kind of contraceptives that produce pelvic congestion. Masturbation is considered to be probably a frequent cause. In seventy-three cases examination revealed pelvic lesions which required gynaecological treatment. Treatment, which averaged ten months' duration, is summarized as follows. (1) Observation alone sufficed in twenty cases; resolution at the end of pregnancy or at the menopause is frequent; under 30 years of age symptoms tend to persist. (2) Pelvic operation; when required, very successful. (3) Non-operative gynaecological therapy of chronic pelvic inflammations, etc.; more successful than in Group 1. (4) Radiation of ovaries led to convincing success in eight out of thirteen cases; dosage was being reduced so as to avoid a sudden menopause, and this might be applicable to younger patients. (5) Treatment by ovarian substance produced no better results than those from simple observation.

185 Therapeutic Use of Pregnancy Urine

According to T. WARSCHAWSKY (*Zentralbl. f. Gynäk.*, November 18th, 1933, p. 2729) urine from patients in advanced pregnancy was first used therapeutically in Russia by subcutaneous and by rectal injection. Schildberg, in Germany, has reported good results from rectal injection in treatment of oligomenorrhoea and of metrorrhagia after gonococcal adnexal inflammation. In twelve patients Warschawsky has injected per rectum twice daily 25 to 50 c.cm. of pregnancy urine, corresponding to 1,000 to 2,000 mouse units of folliculin daily; it was previously boiled to destroy prolactin (which according to Mandelstamm and Tschalkowsky has deleterious effects on the ovary in large doses) and bacterial flora, and was given on the seventh to twenty-fifth days of the cycle. The patients with oligomenorrhoea near the climacteric reported relief from their sleeplessness and functional symptoms.

Pathology

186 Blood Calcium Content in Children

G. CAREDDU and R. CENTO (*La Pediatria*, November 1st, 1933, p. 1349) studied the calcium content of the blood in twenty-six healthy children aged from 1 to 9 years and found that the average amount was 10.1 mg. per 100 c.cm. of serum. Treatment with irradiated ergosterol or ultra-violet rays led to a constant increase of the calcium content. The increase ranged from 6 to 24 per cent. in cases treated by irradiated ergosterol, and from 4 to 21 per cent. in cases in which ultra-violet rays were applied. The highest increase was found in normal children who had a low initial calcaemia—that is, under 10 mg. per 100 c.cm. of serum—while the lowest increase was noted in children with a high initial calcaemia (12 mg. per 100 c.cm. of serum). The percentage increase of calcaemia was greater and more rapid in three rickety subjects who showed a low calcium content of the blood, and in four children with definite tetany in whom the level of calcaemia was also low.

187 Toxicity of Tetanus Toxin

S. MUTERMILCH, M. BELIN, and Mlle E. SALAMON (*C. R. Soc. de Biol.*, 1933, cxiv, 1005) draw attention to an important point in the titration of tetanus toxin. CONDREA and POENARU (*ibid.*, 1933, cxii, 1482 and 1484) recently showed that tetanus toxin diluted in peptone broth had a considerably higher titre than when diluted in saline or distilled water, and concluded that the tetanus bacillus formed a protoxin which was activated by peptone. The present authors have confirmed these observations, but have come to a different conclusion as to their interpreta-

tion. They find that a toxin which kills in a titre of 1 in 100,000,000, when all the dilutions are made in peptone broth, kills only in a titre of 1 in 1,000,000 if the first dilution is made in saline, in a titre of 1 in 500,000 if the first two dilutions are made in saline, in a titre of 1 in 100,000 if the first three dilutions, of 1 in 40,000 if the first four dilutions, and of 1 in 20,000 if the first five dilutions are made in saline. Further observations have shown that tetanus toxin when diluted with saline rapidly becomes inactivated on standing in contact with the air. The higher the dilution is the more rapid is the inactivation of the toxin. Previous work has shown that oxygen has a markedly destructive action on tetanus toxin, and the authors therefore conclude that the presence of peptone in the diluting fluid protects the toxin against oxidation. It follows that for accurate titration of tetanus toxin some protective substance like peptone or serum must be used in the diluting fluid.

188 The Bacteriological Diagnosis of Gonorrhoea

A. BECK (*Zentralbl. f. Bakt.*, December 4th, 1933, p. 281) discusses the difficulties of diagnosing gonorrhoea, particularly in the chronic stages, by microscopical means alone. In this stage true gonococci are not always situated intracellularly, and they are very difficult to distinguish from other Gram-negative organisms. An investigation was made of seventy cases (eighteen male and fifty-two female) in which organisms microscopically resembling gonococci were found in genital or urethral smears. Cultures from every case were made on a medium consisting of equal parts of 2 per cent. nutrient agar and ascitic fluid. Colony formation was studied on 10 per cent. sheep blood agar, and further differentiation of the various organisms isolated was carried out on the usual media. In only four cases was the gonococcus isolated. *M. catarrhalis* was isolated once, enterococci twenty-three times, *Str. viridans* seventeen times, non-haemolytic streptococci seven times, haemolytic streptococci twice, *Staph. albus* forty-eight times, *Staph. aureus* six times, sarcinae eighteen times, *B. coli* fourteen times, *proteus* twice, *P. pyocyanea* once, diphtheroid bacilli nineteen times, and lactobacilli twelve times. Of these organisms the diphtheroid bacilli and lactobacilli caused no trouble, partly because of their peculiar morphology and partly because they are Gram-positive. The remaining organisms, however, the author considers may readily be confused with gonococci. Staphylococci and streptococci are not infrequently found in pairs, and failure to retain the Gram stain is not unusual. Organisms of the *coli* and *proteus* groups may occasionally cause difficulty if they are seen in pairs end on. The author's conclusion is that the definitive diagnosis of chronic gonorrhoea can be made by cultural means alone.

189 A Sex Determination Test

T. J. CURPHEY and ANNE S. ROMER (*Journ. Amer. Med. Assoc.*, November 18th, 1933, p. 1630) have repeated the sex determination test of DORN and SUGARMAN (*ibid.*, cxix, 1659) using a pure-bred strain of New Zealand white rabbits. The latter observers found a correct prediction of the sex of the unborn child in 94 per cent. of eighty-five cases, when changes in the testicles of immature rabbits which had received intravenous injection of pregnancy urine were taken as a criterion. The present authors, however, found that the deductions based on enlargement or not of the testes proved erroneous in many instances, even when the selected optimum age group of rabbits, as defined by Dorn and Sugarman, was employed. They conclude that the age of the experimental animal and the anatomical position of the testes at the time of the investigation play no special part in testicular stimulation. They are satisfied that the urine of pregnant women contains a spermatogenic factor, which, however, appears to have no relation to the sex of the unborn child. They suggest that further investigation would be worth while to determine whether there is some relationship between this spermatogenic factor and toxæmic states of pregnancy.

EPIITOME OF CURRENT MEDICAL LITERATURE

Medicine

190 Normal and Pathological Red Blood Pictures in Old Age

F. LASCH and K. TRIGER (*Med. Klinik*, October 1st, 1933, p. 1346) have analysed the blood counts of 150 patients over 60 years of age suffering from various diseases. They find that a hyperchromic red blood picture is peculiarly common in old age, not merely in Addisonian pernicious anaemia, but in varying types of secondary anaemia and frequently with a normal haemoglobin content. Thirteen cases with a normal haemoglobin but a colour index above 1.05 were further investigated. The mean erythrocyte diameter was within normal limits in all cases; the volume index ran parallel with the colour index; there was achlorhydria in six of the thirteen patients and four showed slight urobilinogenuria. From these findings the authors conclude that this type of blood picture, which they name "hyperchromia of old age," is distinct from and unrelated to Addisonian anaemia. In the last few years Lasch and Triger have observed sixty-four cases of Addisonian pernicious anaemia in patients over 60 years of age. They stress the frequency of this condition in the senium. The clinical picture differs little from that in younger patients, but an aplastic blood picture from marrow exhaustion is more common. Atypical and secondary anaemias are not infrequent, and these are often hyperchromic, response to treatment being usually poor. They have observed several cases of panmyelophthisis (aplastic anaemia).

191 Anaemia and Hepatic Cirrhosis

K. FELLINGER and R. KLIMA (*Wien. klin. Woch.*, October 6th, 1933, p. 1191) have studied forty-eight cases of portal cirrhosis from the haematological aspect. Of these, fourteen cases (34 per cent.) had a normal blood count; thirty (54 per cent.) were anaemic, eighteen of these having a hyperchromic anaemia; and four (12 per cent.) had an erythraemia. On closer analysis it was found that in early cases the blood count is normal, and as the disease preceeds anaemia, first hypochromic, later hyperchromic, was the rule. The four erythraemic cases were in a relatively early stage of cirrhosis, and were apparently of the type described by Mosso as primary erythraemia with secondary cirrhosis. None of the cases in the series had had haemorrhage into the alimentary tract. The hyperchromic anaemia is considered by the authors to be haemolytic in origin, as evidenced by reticulocytosis, hyperbilirubinaemia, and an erythroblastic marrow reaction. The Price-Jones curve is similar to that of Addisonian pernicious anaemia, there is moderate leucopenia, and the anaemia responds to liver therapy.

192 Constitutional Tendency to Thrombosis and Embolism

H. STOSZ (*Deut. med. Woch.*, November 10th, 1933, p. 1699) gives a useful review of recent findings in cases which recovered from post-operative (or other) thrombosis or embolism. The author had himself previously found well-marked deviations from the normal in these cases, principal among which were a diminished serum-globulin content, a diminished coagulation time, and a slow rate of sedimentation of red blood cells. These findings suggested a constitutional tendency to thrombosis and embolism originating in an abnormal condition of the serum colloids. Similar findings were obtained in cases showing dermatographia, respiratory arrhythmia, bradycardia, lymphocytosis, and eosinophilia. Having regard to the fact that adrenaline, thyroid, and pituitary medication produce the reverse picture—namely, increased serum globulin, lengthened coagulation time, and more rapid rate of sedimentation—it is considered that these phenomena represent the result of excitation of the sym-

pathetic. Insulin, regarded as a parasympathomimetic hormone, produces the same changes as are observed in vagotonic subjects. Examination of various theories strengthens the author in his view that those cases developing thromboses or emboli are constitutionally predisposed thereto. The lower globulin content is taken as evidence of a diminished heparin or anti-prothrombin content in the blood, and hence a greater tendency to rapid coagulability. In these patients he considers that we have a liability of the vegetative nervous system, with an overbalance in the parasympathetic direction. It is suggested that as a test for this tendency to thrombosis and embolus formation we should take the diminished rate of sedimentation of the red cells. The possibility of prophylaxis by means of sympatol and thyroid preparations is considered.

193 Epidemic Myalgia ("Bornholm" Disease)*

N. L. CRONE and E. M. CHAPMAN (*New England Journ. Med.*, November 16th, 1933, p. 1097) state that thirty cases of this disease, which he terms "epidemic pleurodynia," first described by Dabney under the name of "devil's grip" in Virginia in 1888, were admitted to the Massachusetts General Hospital between August 1st and 25th, 1933. The patients had come from scattered regions in and around Boston. The ages ranged from 2 to 43 years, the majority being between 10 and 25 years. The sexes were equally affected. The onset was usually sudden, with pain in the lower chest, praecordium, and abdomen, and with a rise of temperature to 102° or 103° F. Headache was frequently present; signs of dry pleurisy were found in two cases, but in the rest examination of the chest was negative. The urine was normal in every case and, with the exception of three who showed a polymorphonuclear count, the blood was normal in all. Recurrences occurred in several cases, in some as long as ten days after the initial symptoms. All recovered.

Surgery

194

Contracted Toes

D. GLISSAN (*Aust. and New Zeal. Journ. Surg.*, October, 1933, p. 149) states that primary contracture of the toes is not an uncommon lesion and is a deformity of young adult life, males being most frequently affected. Although the deformity may be biological and the result of modern conditions, a history of gonorrhoea may be obtained in a number of cases: in these instances the bilateral wasting of legs and feet is always appreciable. All the toes are affected, with the possible exception of the great toe; there is no trace of cavus deformity and no shortening of the tendo Achillis. Symptoms consist of pain beneath the ball of the foot and in the toes, which may be associated with tingling and numbness, cramp of the legs and feet, and awkward gait. Examination shows the toes in hyperextension at the metatarsophalangeal, and in flexion at the interphalangeal, joints. The tendons of the common extensor stand out in relief on the dorsum of the metatarsus, and the flexed toes are capped by reddened skin or callosities. The secondary form is found in association with claw-foot, equinus, and hallux valgus, and may follow burns or injury to the foot. In this form one or two toes and only one foot may be affected. Early cases may yield to conservative treatment, but in advanced cases operation is called for. This comprises division of the long extensors of the toes and removal of a section together with the division of the soft tissues down to the bone. The periosteum and collateral ligaments are separated from the metatarsal bones, and sufficient bone is removed from each inter-

* A description of a Yorkshire outbreak of "Bornholm" disease was printed in the *Journal* of November 4th, 1933 (p. 817).

phalangeal joint to straighten the digits and to ensure ankylosis in a straight position. The toes are splinted and fixed in plaster-of-Paris for six weeks, after which the patient is encouraged to walk, a splint being worn at night for a further six months.

195 Adrenal Sexual Precocity

L. P. PLAYER and H. LISSER (*Urol. and Cut. Rev.*, November, 1933, p. 758) record the case of a boy aged 4 years and 11 months whose bone age was between 12 and 13 years. He was tall and large for his age, though not obese. The external genitals were those of an adult. He had the beginnings of a moustache, a little axillary hair, and plentiful pubic hair. The prostate was of almost adult size, and its secretion contained much lecithin and many spermatozoa. He had frequent erections and many nightly emissions. Pyelography showed a round tumour above the left kidney which depressed the upper calyces. A diagnosis of left adrenal cortical tumour was made and confirmed by operation, when a well-encapsulated mass the size and shape of a large apple was removed. Histologically this was composed of rapidly growing adrenal cortical cells. When seen twenty months after the operation the boy was in good health, and showed the following changes of endocrine abnormalities. The axillary hair had vanished, the moustache and pubic hair had thinned somewhat, the boy was more childish in appearance and demeanour, and though the external genitalia had not diminished in size erections and emissions had been rare since the operation. The writers had found eight other instances of sexual precocity in boys in which an adrenal cortical tumour was found at necropsy. In three of these operation was attempted, but the tumours were inoperable in two. In the other case the tumour was removed, but death took place twelve hours after the operation. The present case is therefore the first of the type in which survival had followed removal of an adrenal cortical tumour.

196 Occupational "Fractures" in Soldiers

SCHERF (*Zentralbl. f. Chir.*, November 25th, 1933, p. 2739) alludes to cases of metatarsal or "march" fractures, in which soldiers were found to have callus without history of fracture of the metatarsus as a reaction of healthy bone to long-continued pressure from similar, repeated movements. As possibly coming in the same category of reinforcement zones ("Umbauzonen"), or possibly as examples of spontaneous fractures, he describes nine cases in which recruits had pain, tenderness, and radiological signs of transverse fracture and callus formation at the junction of the upper and middle thirds of the fibula. No accident had occurred, but the exercise of jumping with the hips and knees maximally flexed had been sedulously practised. Displacement was present in one case only, and was regarded as secondary. Full duty could be resumed within a few weeks.

Therapeutics

197 Treatment of Urinary Tract Infections with Dyestuffs

P. SZRGÖ (*Med. Welt*, November 18th, 1933, p. 1644) reports the successful control of infections of the urinary tract with a new preparation, neotropin, which is an azo-dye of the pyridine series, and is administered per os. This substance possesses the important property of being rapidly excreted, 82 per cent. being removed by the urine in twenty-four hours, and only minimal amounts being excreted by the intestinal tract. The maximum concentration in the organism is reached in some four hours after ingestion, the urinary maximum occurring between the third and fifth hours. The bactericidal action of this preparation is so intense that dilutions of 1 in 10,000 are said to kill *B. coli* and staphylococci. Since the substance is so rapidly excreted it is necessary to adjust the times of administration so that lethal concentrations are available in the urinary tract. Restriction of fluid intake,

combined with the use of a diuretic, will aid in attaining the optimum conditions for effective bactericidal action during excretion. The drug is well tolerated, and colours the urine yellow; it may leave stains, but these are easily removed with soap and water. Neotropin possesses a strong penetrating power and a great affinity for tissues. The author recommends its use in all cases where catheterization is undertaken. In cases where local treatment is impossible or too painful—for example, congestion of mucous membranes, tenesmus, burning pains, etc.—the use of neotropin is particularly valuable. The absence of irritation is an important matter in the treatment of vesical catarrh, most other disinfectant remedies producing considerable pain and spasm. In a considerable series of cystitis cases due to a variety of causes the author reports excellent results with this preparation. In addition to the treatment with neotropin the patients were kept in bed, given a diet free from high seasoning and alcohol, and also had warm hip baths.

198 Parathyroid Extract in Cardiac Therapy

ERNST HAMMERSCHLAG (*Med. Klinik*, December 8th, 1933, p. 1681) reports on the use of parathyroid extract in cases of cardiac decompensation of muscular and valvular origin as well as in cases of angina pectoris due to coronary sclerosis. The author's reasoning is based upon the fact that loss, or insufficiency, of the parathyroid gland induces tetanic phenomena and the syndrome known as "spasmodic diathesis," the most prominent symptoms of which are vascular spasms. The function of the parathyroid gland thus appears closely connected with the state of innervation of the vascular system. As the administration of parathyroid extract gives excellent results in tetanic affections and their sequelae, and as, on the other hand, certain effects of cardiac insufficiency show a close resemblance to tetanic symptoms, the author attempted the administration of parathyroid extract in cardiovascular therapy as an auxiliary means of dealing with the conditions caused by insufficiency or vascular spasms—though only in addition to and not in place of the usual cardiac remedies. The preparation used was the parathyroid extract manufactured by the Sanabo-Chinoin works in Vienna, and containing 20 Collip units per c.cm. Describing six cases in detail, the author concludes, that the results obtained by such auxiliary parathyroid medication are sufficiently encouraging to justify the continuation of experiments in this direction, and adds that in no case have undesirable effects of the method been observed.

199 Auto-haemotherapy (Intravenous) in Gonorrhoea

A. INGMAN (*Finska Läkarsällskapets Handlingar*, November, 1933, p. 1051) reports his experience with some forty cases of gonorrhoea, complicated by epididymitis, prostatitis or arthritis, in which intravenous injections of the patient's own haemolysed blood were given as a form of protein shock treatment. A 20-c.cm. syringe, containing 14 c.cm. of recently sterilized distilled water, is used. After its needle has been introduced into a vein of the arm, 7 c.cm. of blood is aspirated and mixed with the distilled water by the rotation of the syringe on its own axis while the needle remains in the vein. (It has been found that after thirty to sixty seconds 90 per cent. of the erythrocytes are haemolysed by contact with water.) From one-third to the whole of the contents of the syringe is injected after this interval into the vein before the needle is withdrawn. In this way over 200 injections were given by the author quickly, painlessly, and without any mishap. He tabulates his cases in five different groups, the first four of which (twenty-three cases) concern epididymitis in different stages, the fifth and last including cases of gonorrhoeal arthritis. Occasionally, the patients complained of a short bout of pain in the affected testicle following the injection and interpreted as a local reaction to it. In most cases of epididymitis there was definite improvement on the day after an injection. It provoked a slight rise of temperature, which was greatest after the first or second injection. There were no other general reactions such as giddiness, headache,

etc., nor was there any sign of an old gonorrhoeal focus being stirred into new activity. The author states that though the injections were easy and cheap and were followed by a general improvement, it is doubtful whether they did much to hasten local reabsorption. A drawback was the advisability, amounting almost to a necessity, of controlling them by estimating the rate of sedimentation of the erythrocytes before each injection. When this rate is excessive (negative phase) an injection should, it is stated, not be given.

Neurology and Psychology

200

Trauma in Encephalitis

A. M. RABINER (*New York State Journ. Med.*, July 1st, 1933, p. 796) attempts to estimate the influence of trauma in acute and chronic encephalitis. He cites examples from the literature, and records a series of nine personal cases which have led him to certain definite conclusions. He is satisfied that, following an injury to the head in which there is present some evidence of intracranial involvement, the minimal degree being a cerebral concussion, a later-developing epidemic encephalitis syndrome must be regarded as having been influenced in its production by the trauma. Rabiner gives illustrations of cases in which it seems certain that trauma, whether recent or remote—in one instance seven years previously—must have been responsible for setting up a pathological condition which permitted the entry into the central nervous system of the infectious agent causing acute epidemic encephalitis. He remarks that a patient who has had in the past an attack of this disease may have chronic manifestations, such as Parkinsonism, initiated or produced by an injury to the head; but, again, such an injury must have been severe enough to give rise to the picture of cerebral concussion. A partial clinical evidence of chronic encephalitis, such as a tremor of the hand or loss of associated movements, may be regarded as indicative of the full syndrome developing. If the patient is then injured, the subsequent advance in symptoms is not to be considered attributable to the trauma. An injury to any part of the body other than the skull, particularly when not associated with signs of cerebral concussion, is not to be considered as playing any part in the clinical course of epidemic encephalitis.

201 Physical Derangements in Cyclothymia

C. ROGGENBAU (*Med. Welt*, July 8th, 1933, p. 952) considers that body-weight variations in cyclothymia are due to (a) mental disturbances and (b) physical derangements, such as anorexia. These interact through the vegetative nervous and endocrine systems. In several cases anorexia followed glucose administration. Changes in gastro-intestinal activity are frequent; they are attributable to disturbances of the autonomic mechanism. Metabolism is accelerated (usually) or retarded by similar causes—autonomic hypersensitivity and endocrine imbalance. The endocrine and autonomic nervous systems are connected intimately and reciprocally. The degree of metabolic disturbance depends on organic sensitivity and functional response to stimulation. The functional activity of every endocrine gland should be tested for deviations from normality, and to determine whether the response to psychological influences is pathological. During depressive phases thyroid activity may be accelerated or diminished—the patient's symptoms simulating those of exophthalmic goitre or of myxoedema. The secretion of "gonadotrope" hypophyseal hormone is readily increased or diminished. Gonadal derangements occur in nearly 50 per cent. of all cases. In some depressive states increased electric irritability was observed—unconnected with parathyroid dysfunction, since the calcium content of the plasma remained normal. Manic and depressive phases were unaffected by monosaccharide administration. Definite hyperglycaemia occurred generally, with lengthening of the curve, as in thyrotoxicosis

—probably due to sympathetic stimulation. Glycosuria is a common symptom, unconnected with hyperglycaemia, but due to constitutional factors—for example, increased permeability (to sugar) of the renal epithelium. The cholesterol blood content is generally high, and arteriosclerosis is a frequent complication, although this is not associated with chronic nephritis. Further study of the metabolism of the endocrine system and its relations with the autonomic nervous system may furnish the key to these complex problems.

202

"Retraction Nystagmus"

E. GAMPER and J. KUBIK (*Med. Klinik*, August 18th, 1933, p. 1134) describe a case of cerebral tumour which showed the sign which has been named "retraction nystagmus." Kubik describes this sign thus: "When an eye movement is attempted a backward retraction of the bulb occurs either in place of, or as a concomitant to, the attempted movement." The sign was first described by Koerber in 1903, and since then six further cases have been recorded. The authors consider this rarity as more apparent than real, as, when nystagmus is present, it is easy for the retractor component of the movement to evade observation. The case reported in this paper is one of a pinealoma, and the march of signs and symptoms allowed the authors to deduce the exact situation of the causative lesion. This point is on the dorsal aspect of the mid-brain, slightly caudal to the oculomotor nuclei and close to the aqueduct. "Retraction nystagmus," although of great rarity, is thus of importance as it constitutes a definite localizing sign.

Obstetrics and Gynaecology

203

Treatment of Pruritus Vulvae

C. D. KENNEDY (*Edinburgh Med. Journ.*, September, 1933, p. 125) records fifteen cases of pruritus vulvae which were treated with "A.B.A.," a suspension in an oily medium of 3 per cent. amido-benzoic-acid-ethyl-ester, 5 per cent. benzyl alcohol, and 10 per cent. ether. This combination of local anaesthetics of low toxicity exerts a pronounced action, and there is no initial burning. Kennedy gave weekly injections of this mixture just underneath the skin in such a way as to ensure that a fan-shaped area was dealt with. If the drug is injected into the deeper tissues there is some danger of abscess formation. At each successive injection a different zone is treated, until the whole vulvar region has been infiltrated. The number of injections in a case ranged from three to thirty-three. The quicker the patient responded and the fewer were the necessary injections, the better was the result. The general health improved in ten out of the fifteen cases. Absolute freedom from irritation ensued in five cases, and in another five the itching became much less severe, only recurring after long intervals. Four were slightly improved, there being definite intervals of freedom. In one case no benefit was obtained. The author remarks that pruritus vulvae may occur independently of any accompanying general or local condition, and must therefore be viewed in many cases as a disease rather than a symptom. There is a close relation between pruritus and the menopause, and endocrine deficiency may be an aetiological factor. Although not invariably successful, treatment with "A.B.A." would seem to merit trial.

204

Loss of Weight in the Newborn

I. N. KUGELMASS, RUTH E. L. BERGGREN, and MILDRED CUMMINGS (*New York State Journ. Med.*, December 1st, 1933, p. 1365) believe that too little attention is paid to the loss of weight in the newborn, which they think results from dehydration and semi-starvation. They find that this initial loss of weight can be prevented by the administration of a solution composed of 6 per cent. gelatin (pH 6.2), 3 per cent. glucose, and 0.5 per cent. sodium chloride at two-hourly intervals during the first twenty-four hours after birth. It is claimed that the gelatin hydrates the

blood and tissues, that it raises the body heat by virtue of its specific dynamic action, and that it reduces the clotting time. The dextrose brings the neo-natal hypoglycaemia to the normal. The sodium chloride raises the initial low blood chloride content and favours hydration. The authors found that when newly born infants were placed on this treatment their average loss of weight was 1.7 per cent.—in very sharp contrast with the usual 7 per cent. They add that the characteristic clinical picture of the infant results from birth shock, and that this is more effectively combated by a hydrating solution than by milk mixtures during the first two or three days of life. Prevention of the loss of weight in the newly born child promotes the rapid disappearance of the so-called physiological apathy, somnolence, and stupor, which are secondary to birth shock, and associated with a compensatory acidosis. E. A. RIESENFELD (*ibid.*, p. 1372) believes that chilling at the time of birth is an important factor in this loss of weight. He found experimentally that it was much less when artificial heating by lamps was arranged, particularly in the case of premature children.

205 Pregnancy Tetany and Eclampsia

According to E. KLAFTEN (*Zentralbl. f. Gynäk.*, December 9th, 1933, p. 2915) tetany in connexion with pregnancy, although rare, has a mortality of some 5 to 7 per cent.; it may recur in successive pregnancies in those having latent hypoparathyroidism. Some cases of tetany in or after labour are combined with apparently eclamptic convulsions, and are ascribed by KlafTEN to hyperventilation of the lungs; and some cases of non-toxic or tetanoid eclampsia, with no oedema, little or no nephropathy, and favourable prognosis, are of similar origin. Accordingly, KlafTEN agrees with Seitz's distinction between toxic and tetanoid eclampsia. He finds, however, that the measurement of galvanic muscular excitability is not conclusive in diagnosis between the two, for a few cases of the former have increased excitability. As a result of tachypnoea and hyperventilation either tetany, with carpopedal spasm and/or laryngeal spasm on the one hand, or non-toxic eclampsia on the other, may be produced in or after labour. According to KlafTEN the conditions justifying termination of pregnancy in patients with tetany are failure of medical treatment, affection of respiratory muscles, impairment of consciousness, intractable tachycardia, or signs of liver or kidney affection. This treatment will probably be less frequently required since the introduction of improved preparations, such as the gluconate, for calcium treatment.

Pathology

206 Congenital Syphilis and Mental Deficiency

K. C. L. PADDLE (*Brit. Journ. Child. Dis.*, October-December, 1933, p. 49), after a review of the literature, records his observations on the relation between congenital syphilis and mental deficiency in a paper based on the study of 402 cases of low-grade mentally defective children. The blood Wassermann reaction and the Meinicke macro-clarification reaction were done, together with the Wassermann reaction, Lange's colloidal gold test, Pandey's test, and cell estimations on the cerebro-spinal fluid. Forty-six gave positive results in the blood or cerebro-spinal fluid, and 356 were entirely negative. Of the forty-six cases thirty-five were considered to be congenital syphilitics. Two of the 356 cases were also regarded as congenital syphilitics on clinical grounds, so that the total incidence of hereditary syphilis was thirty-seven cases (9.2 per cent.). The Wassermann reaction in the blood was in the majority of cases much more sensitive than the Meinicke macro-clarification reaction—contrary to what appears to be the case in adults. In five cases the cerebro-spinal fluid showed strong paretic types of curve, associated with positive Wassermann reactions, and increase of cells and protein, but none of the cases could on clinical grounds be regarded as examples

of juvenile general paresis. The cerebro-spinal fluid of twenty mongols failed to give any special type of curve with the colloidal gold reaction. The congenitally syphilitic male defectives showed marked retardation of descent of the testes in 60 per cent., as compared with 39 per cent. in a comparable group of non-syphilitics.

207 Late Effects of "Thorotrast" used in Radiological Investigations

M. E. JÖRG and J. A. AGUIRRE (*Actualidad Med. Mundial*, No. 3, 1933, p. 277) relate their experience of the delayed effects of this substance when used according to the technique described by Radt. Believing it to be a radioactive irritant, they issue a warning against its employment. Within six months after its administration in healthy animals they found that splenic and hepatic cells laden with thorium had been carried by the blood stream into the lungs, where they had produced granulomata, and were but rarely eliminated by the bronchi. Escaping through the pulmonary filter, a few regained the liver and spleen and produced the formation of huge giant cells surrounded by a fibrosis which later caused a necrobiosis of the contents. This irritative process engendered granulomata in the hepatic sinuses and lymphoid foci in the porto-biliary spaces. In the spleen the substance was stored in all elements, but especially in the centres of the Malpighian follicles, impairing their functions and making them appear like great wreaths of lymphocytes in evolution surrounded by capsules of hyperplastic cells. Six months after the injection the liver, blocked by the metal, showed a metaplastic regeneration of the reticulate fibrils, either as an irritative sclerosis of Glisson's capsule or as fibrous foci arising from granulomata. Fourteen months after injection the metal was still encysted in the giant cells already described, which are surrounded by evidence of granulomatous reaction; but the prevailing picture is one of vacuolation and albuminoid degeneration of the liver cells, with karyolysis and compression of the capillaries.

208 Bachman Skin Reaction in Trichinosis

R. A. KILDUFFE (*Amer. Journ. Med. Soc.*, December, 1933, p. 802) states that in 1828 Bachman described an intradermal reaction in experimental trichinosis consisting in the injection of a 1 per cent. solution of powdered trichinella larvae. The reaction, which ranges from a slight area of oedema to a well-defined haemorrhagic area, occurs within a week of injection. Kilduffe tried this test in thirty-three cases of human trichinosis, and came to the following conclusions: (1) the demonstrations of eosinophilia is not only technically simpler than the demonstration of the skin test, but is always feasible, whereas the skin test is not; (2) in point of delicacy and constancy of appearance eosinophilia is a reliable index of trichinosis in the human subject; (3) the Bachman skin test presents no practical advantage over the demonstration of eosinophilia in the study of human trichinosis.

209 Local Immunity to Pulmonary Tuberculosis

R. R. VILLANOVA and J. P. CANALIS (*Bull. de l'Acad. de Méd.*, November 28th, 1933, p. 581) suggest the existence of some substance in the pulmonary tissue capable of immunizing it against microbial invasion. In this connexion, Köbert has investigated silicic acid. Similar experiments have been made by the present writers. As calves possess a great predisposition to, and sheep a great resistance to, tuberculosis, the silicon content in the healthy lungs of seventy of these animals was estimated. The first twenty analyses showed an average content of 0.246 gram in the calf and 0.41 in the sheep; the remaining fifty analyses gave analogous results. These confirm Köbert's observations and, further, show that the quantity of silicon fixed in the pulmonary tissue is in strict relation with natural immunity against tuberculosis, and that increase of this amount produces an increased resistance to infection. Villanova and Canalis deem this to be of prophylactic and curative importance. Further animal and clinical experiments will be reported at a later date.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

210 Innervation of the Bladder and Colon

As the result of experiments on cats, ADAMSON and AIRD (*Brit. Journ. Surg.*, October, 1932) reported that megacolon can be produced by simple section of the erector nerve of Eckard. R. FONTAINE and M. BÉRARD (*Presse Méd.*, January 17th, 1934, p. 81) do not agree with this finding, nor with the classical teaching that section of this nerve alone causes a definite paralytic distension of the colon and bladder; this latter view is shared by Leriche. The extrinsic innervation of these organs is partly sympathetic, partly parasympathetic; the former is derived from the superior hypogastric plexus and the two lumbar sympathetic chains, the latter from branches from the second to the fourth sacral roots, especially the third (the erector nerves of Eckard). These two sets of fibres unite lower down into a single ganglion (the hypogastric); therefore, section of only one set must be made above this ganglion. Experiments on dogs are described; according to these, section of Eckard's nerves causes only a transitory vesico-colic paralysis, normal conditions being restored by the action of the rich intramural nerve supply of both organs. The present authors maintain that this intramural system, reinforced by motor fibres from the sacral cord, ensures all normal vesical functions; to the superior hypogastric plexus, the sympathetic part of the vesical innervation, they ascribe a merely sensory function. They therefore suggest that in painful cystitis necessitating surgical intervention the latter should be directed to the superior hypogastric plexus and not to the ganglion; as the sympathetic furnishes the sensory innervation of the bladder, its section should procure the maximum of relief.

211 Intoxication Coefficient in Carbon Monoxide Poisoning

BALTHAZARD and MELISSINOS (*Paris Méd.*, November 18th, 1933, p. 393), who report a number of cases, contend that carbon monoxide poisoning can be rightly considered to be the cause of death only in cases where the "intoxication coefficient" (ratio of carboxyhaemoglobin to total quantity of haemoglobin) is not below 0.42. Lower values in lethal cases denote the existence of accessory causes of death. In genuine carbon monoxide poisoning the only proper antidote is oxygen, and every other therapy (for example, hypodermic injections of sodium hyposulphite) is to be condemned as based on erroneous notions concerning the chemistry of this intoxication.

212 Prognosis in Pulmonary Tuberculosis by Sedimentation Test

S. BERG (*Nord. Med. Tidskrift*, November 25th, 1933, p. 1426) finds that though the rate of sedimentation of the erythrocytes is no specific test, being merely indicative of the degree of intensity of a morbid reaction, it is remarkably reliable in prognosis in this disease. When patients are admitted to the sanatorium with a sedimentation rate below 30 to 40 mm., the odds are that this rate will become still slower and that clinical improvement will follow. On the other hand, when the rate is above this figure on admission, there is a considerable likelihood of its becoming still higher, or fluctuating wildly, what time the patient becomes clinically worse. An exception to these generalizations is to be found in those cases in which it is possible to induce a pneumothorax. Here an originally high sedimentation rate may be changed to a normal rate with corresponding clinical improvement. The author has investigated the subsequent fate of 171 patients five years after their discharge from a sanatorium

in 1922. They were classified according to the rate of sedimentation on discharge in the four following groups: 1 to 6 mm., 7 to 25 mm., 25 to 50 mm., and over 50 mm. In the first group the mortality was only 3 per cent. In the succeeding groups it was 32, 80, and 95 per cent. respectively. It will thus be seen that the prognosis for a sanatorium patient on discharge is good or bad according as his sedimentation rate is under or over 25 mm. Under this figure the mortality in the author's material five years after discharge was only 16.5 per cent., whereas over this figure it was 86 per cent. Though the sedimentation test is not absolutely impeccable, events are likely to justify it even in those cases in which other prognostic signs give it the lie.

213 Epidemic Myalgia

R. HUSS (*Svenska Läkarsälls. Förhand.*, November 30th and December 31st, 1933, p. 559) gives an account of an epidemic of myalgia which occurred in Sweden in 1931, and reached its maximum in August and September. There were no fatal cases, in spite of the stormy and painful character of the disease, which in some cases led to the diagnosis of "acute abdomen" and to a laparotomy. As the disease was not notifiable and the slighter cases escaped medical supervision, only an approximate estimate could be formed of the extent of the epidemic. It is probable that there were at least 12,000 cases. The epidemic spread in a jerky fashion along the coastal districts, avoiding for the most part large towns, such as Stockholm and Gothenburg, although they were in the infected zone, and appearing inland only in a few places which were low-lying and near important watercourses. The sex incidence was impartial, and a common age incidence was between 15 and 30. In addition to the violent pain in the lower chest and abdominal muscles, there were the following manifestations observed more or less frequently: vomiting, slight shivering attacks, headache, constipation, pain in the muscles of the back, fever, delirium, excessive sweating, diarrhoea, cough, orchitis, and dry pleurisy. The comparative immunity of the large towns was at variance with the theory of a contact infection from one person to another. The occurrence of the epidemic in the summer months suggested the intermediary of an insect as vector of the disease. According to a third hypothesis, the preference shown by the epidemic for coastal areas pointed to its being a water-borne disease. In this connexion it was noted that gastrointestinal symptoms were far more common than catarrhs of the respiratory tract. The explosive character of the epidemic in several areas was also suggestive of an infected water supply.

Surgery

214 Rupture of Operation Scars

H. FLÖRCKEN and E. KOBEL (*Deut. med. Woch.*, December 22nd, 1933, p. 1886) have reinvestigated ninety-six of the 158 cases operated on in the period 1921-9 for rupture of operation scars. In fourteen of the ninety-six cases a relapse had followed. In six of these cases the patients had been very fat, and adequate measures had not been taken to reduce their weight before the operation. According to the authors the incidence of rupture of post-operative abdominal scars varies greatly according as the abdominal wall is closed at once or not. In the latter case the frequency of such post-operative ruptures ranges from 12 to 20 per cent. with different authors. In the present material the overwhelming majority of the ruptures occurred within the first year after the operation. Hence Flörcken and Kobel's recommendation that patients should present themselves for re-examination after a laparotomy within six months of

it and again within the year, in order that such ruptures may be promptly discovered—they are apt to be completely overlooked by the patients themselves. Such ruptures require an operation both when they are small (as they are liable, surely but slowly, to become larger, and as the operation is usually a simple matter) and when, though large, they are complicated by signs of incarceration, digestive disturbances, or other discomforts. On the other hand, an operation is contraindicated for very large ruptures for which there is little prospect of a complete and effective repair. Dietetic treatment which effectively reduces weight may, however, render such cases operable. Disease of the vascular, respiratory, and renal systems is also a contraindication, but diabetes must be severe to be included among the contraindications. Among the authors' 138 cases there was only one operative death.

215 Treatment of Lymphogranuloma Inguinale

F. KALZ and F. SAGHER (*Derm. Woch.*, December 16th, 1933, p. 1754) describe the course and treatment of thirty cases of lymphogranuloma inguinale seen in Prague in two years: the diagnosis was confirmed by the Frei reaction, which was found to be somewhat modified in cases of seropositive syphilis. The best results were obtained from injections of the serum of convalescents. Local antiseptic treatment and treatment by antimony preparations were practically ineffective; local excision, although successful in small isolated buboes, was followed by protracted fistula formation in other cases. Solganal treatment was associated with a mild course of the affection, but with a long duration and a tendency to recurrence. X-radiation was a useful accessory treatment, and was followed by massive necrosis or accelerated softening. The average duration of treatment after injections of convalescent serum was six weeks: they were given at three or four days' intervals, intramuscularly or subcutaneously, in average doses of 10 c.cm. and total doses of 60 to 150 c.cm.

216 Simple Haemorrhagic Proctitis and Proctosigmoiditis

T. E. HESS THAYSEN (*Hospitalstidende*, December 7th, 1933, p. 1181) records twenty cases of a disease which until a few years ago was given little consideration and was often confused with other conditions, notably ulcerative colitis. He states that, with the help of the rectoscope and microscope, simple haemorrhagic proctitis and proctosigmoiditis can be made to present a well-defined picture with a characteristic clinical course. Fourteen of the patients were women, and the ages of the twenty patients were within the limits of 19 and 59 years. In only ten cases was there a previous history of other intestinal ailments—usually constipation. In the lighter cases the only symptom was haemorrhage, ranging from streaks of blood on the motions to a tablespoonful of blood escaping either directly after defaecation or independently of it. Other symptoms were slight stabbing or smarting in the rectum, with tenesmus and constipation. In the absence of fever, dyspepsia, abdominal pain, and anaemia, patients are apt to neglect this ailment for years. The history of bleeding promptly suggests haemorrhoids, and the correct diagnosis can only be made by rectoscopy, which not only reveals the extent and severity of the disease, but also distinguishes it from haemorrhoids, fissure, cancer, ulcerative proctitis, etc. The condition reacts promptly and satisfactorily for some time to astringent solutions containing tannin or silver nitrate, and to painting with silver nitrate and dusting with bismuth. But the disease is very liable to recur; it may do so after a symptom-free interval of four years. The treatment the author found most satisfactory was the introduction of 300 to 500 grams of a 1 per cent. solution of "yatren" into the rectum in the evening, after a preliminary lavage, with retention if possible overnight. After two months of such treatment an at any rate temporary cure is effected.

Therapeutics

217 Sanocrysin in Diseases of the Joints

K. SECHER (*Nord. Med. Tidsskrift*, November 18th, 1933, p. 1388) is very favourably impressed by the results of intravenous injections of sanocrysin in various rheumatic diseases of the joints. In addition to his many private and ambulatory patients he has treated a large number of patients in a hospital in Copenhagen, and the following results were observed at the time of discharge: thirty-two cures, marked improvement in thirty-nine cases, some improvement in nineteen, and no effect in seventeen cases. In the first category there were nine cases of chronic progressive primary polyarthritis, six of chronic rheumatic polyarthritis, twelve of rheumatic fever, and five of other "rheumatic" manifestations. When little or no benefit was obtained the cases were almost invariably of long standing. Owing to the tendency of this class of case to react violently, the dosage should be cautious; the first two injections should be of 25 cg. each, and the next two of 35 cg. each. It is seldom necessary to give more than 50 cg. at a time. The interval between the first two injections should be four or five days, and thereafter the interval should be prolonged to six or seven days. As a rule the best therapeutic effects were achieved in response to the most violent reactions, general and focal. The author, who controls his cases by blood sedimentation tests, concludes that this treatment warrants more favourable attention, as it is effective in the most serious of all the rheumatic lesions of the joints—chronic progressive primary polyarthritis. One of his private patients, a woman aged 40, who had been ill for eight years and could not get up from a chair without help, was able, after sanocrysin treatment, to ride for several hours at a time and to dance.

218 Pyretotherapy in Gonorrhoeal Arthritis

T. DUMITRESCO and C. PETREA (*Bull. et. Mém. Soc. Méd. des Hôp. de Paris*, December 8th, 1933, p. 1480) record five cases of gonorrhoeal arthritis in which cure was obtained by injections of the antichancereous vaccine of Dnielcos. The initial dose employed was 225 millions, subsequent doses being from 335 to 675 millions. Equally remarkable results have been obtained by C. Richet, jun., in cases of arthritis of other origin (post-anginal, post-pneumonic, post-abortion, etc.) by a similar pyretogenic treatment. Though in the cases recorded this treatment was given one to two months after the onset of the arthritis, and after other measures had failed, the present authors emphasize the importance of early treatment, and also state that the more intense and persistent the fever produced the better will be the results.

219 Coramine as an Antidote to Narcotics and Other Poisons

C. CLEMMENSEN (*Ugeskrift for Læger*, December 14th, 1933, p. 1329) has tested for a year at his hospital in Copenhagen the claims recently made in Berlin for coramine (pyridine-carbonic-acid-diethylamide "Ciba"). During this year every one of the sixty-nine cases (aged from 11 to 83 years) admitted to hospital for poisoning by gas (eighteen cases), barbituric acid preparations (twenty-eight cases), morphine, and other drugs was given coramine treatment in addition to older routine measures such as the administration of caffeine, camphor, etc. The coramine was injected on admission, but usually only after the stomach had been washed out. When the degree of poisoning was slight it was given intramuscularly (5 c.cm.), but all of the fifty-six patients admitted to hospital unconscious or excessively drowsy received it by the intravenous route (5 to 15 c.cm.). The largest single dose was 15 c.cm., and the largest total dosage for the same patient was 25 c.cm. None of the thirteen patients whose poisoning was slight and who were given intramuscular injections died; but among the fifty-six severe cases there were sixteen immediate and two remote deaths, which occurred after a few days, and

were due to infarct of the brain and uraemia respectively. The average interval between the taking of a poison and admission to hospital was twelve hours in fourteen fatal cases, whereas it was only seven hours in twenty-five cases ending in recovery—an observation stressing the value of early treatment. The effect of the coramine was often instantaneous, and comparable to that following an unexpected deluge of cold water on the head; the patient would gasp, breathe deeply, and turn about as if in self-defence, groaning, sneezing, coughing, etc. In six cases the action of the coramine was strikingly successful and durable, and there were only seven patients who did not respond at all to it. Between these extremes was the majority of the patients who derived some benefit from this treatment. It seemed to be more effective in poisoning by gas and morphine than in barbituric acid poisoning. Clemmesen does not discuss the rationale of the treatment.

220 Treatment of Peptic Ulcer

P. MORETTI and N. C. MANNO (*Il Morgagni*, November 26th, 1933, p. 1459) record twenty-one cases of gastric and duodenal ulcer in patients aged from 23 to 60 treated by injections of pepsin, or of pepsin alternately with sodium benzoate. The injections were given intramuscularly every other day in doses of 2 c.cm. of a 10 per cent. solution of pepsin with or without intravenous injections of 2 c.cm. of a 25 per cent. solution of sodium benzoate. The injections were given in from one to three series of twelve injections with a few days' interval between each series. It is stated that the result of the treatment was a considerable improvement in the symptoms and general condition, though without any corresponding change in the radiological picture. It was therefore difficult to say whether the treatment was responsible for the clinical improvement.

221 Laryngoscopy and Aspiration in Laryngeal Diphtheria

L. E. HAMON (*Thèse de Paris*, 1933, No. 518) records twenty-five cases of diphtheria in children, aged from 7 months to 9 years, treated by direct laryngoscopy and aspiration. Twenty recovered and five died. Hamon's conclusions are as follows. Direct laryngoscopy in the child is a simple, easy, and rapid method that does not cause any trauma. It is the first step in the method of aspiration of the diphtheritic membrane, which is applicable in all cases in which intubation is required. Aspiration, moreover, is the only logical method for combating the mechanical obstruction caused by the membrane in the tracheo-bronchial tree. The technique of aspiration is simple, no anaesthetic and no complicated instruments being required. It is indicated in all cases of tracheo-bronchial diphtheria, especially when there is continuous recession accompanied by paroxysmal attacks of dyspnoea. The immediate results are decidedly superior to those of intubation, and the remote results are excellent as the larynx is able to resume its normal function a few weeks at most after the aspiration.

Anaesthetics

222 Dental Anaesthesia

L. T. CLARKE (*Birmingham Med. Rev.*, December, 1933, p. 236) admits the value of the intratracheal method of administering nitrous oxide in dental surgery, but protests against its routine use. Even with careful aseptic precautions there is always some chance of conveying infective material from the mouth and nasopharynx past the vocal cords. Moreover, unless the patient is deeply anaesthetized before the passage of the catheter, there is some danger of injuring the vocal cords; hoarseness may persist for as long as three weeks after intratracheal narcosis. The convenience of the administration may also tempt the surgeon to undertake a more major operation than should be performed in a dental chair. If oxygen is to

be employed, the apparatus should be well designed and in good working order; otherwise it is best not to attempt to give it. Clarke points out that there is as much liability to severe surgical shock in major dental operations as in the operations of general surgery, and nursing homes rather than dental surgeries are the appropriate places for them. Preliminary scaling and the judicious use of mouth washes and nasal douches should not be omitted when indicated lest post-anaesthetic complications multiply. Premedication is generally unnecessary, but atropine should be injected if ether is to be employed. The barbituric acid derivatives are valuable in conjunction with local anaesthetics. In small doses nembutal is useful to render the patient placid. For major operations of short duration ethyl chloride followed by ether and oxygen is most convenient, about fifteen minutes of analgesia being thus obtainable. For longer operations the intratracheal method is used. When gas and oxygen is given after nembutal, less anaesthetic is required, and the proportion of oxygen can be increased, even up to 40 per cent. Clarke commends ethyl chloride as the best anaesthetic for children, given on an open mask or in a bag. Cyanosis is marked in them, as also in old persons, and the addition of oxygen is often a great advantage. Gas must not be pushed too far in the aged because of the danger of apoplexy. In cases of compensated heart disease special care must be taken to avoid inflicting strain; cyanosis appears early. Should the pulse become slow or intermittent, the anaesthetic must be stopped, but the judicious use of oxygen should have prevented this.

223 Intravenous Sodium Evipan Narcosis

H. LÖWENBURG-MARQUIS (*Schmerz Narkose-Anaesthesia*, November, 1933, p. 55) has found intravenous evipan narcosis satisfactory for short operations of twenty minutes or less, but does not recommend it for laparotomies, knee-joint operations, or others in which very full muscular relaxation is required. In young muscular males a supplementary injection or ether inhalation was always found necessary. Seven c.cm. of evipan were given to an adult of 50 kg., with an additional 0.5 c.cm. for each 5 kg. body weight above this; not more than 3 c.cm. were injected in a minute. The injections were followed by temporary reduction in the frequency and depth of respiration, acceleration of pulse, and (usually) fall of blood pressure. Cyanosis was noted in eight cases of a series of fifty. The forty patients who received evipan alone were afterwards free from nausea, vomiting, headache, and local thrombosis. Supplementary evipan injections were given in several instances, the maximum total dose being 14 c.cm. One patient weighing 56 kg. had three injections totalling 12.5 c.cm. for an operation lasting sixty-nine minutes.

224 Lumbar Anaesthesia

I. PHILOPOWICZ (*Zentralbl. f. Chir.*, December 2nd, 1933, p. 2793) discusses the merits and demerits of recent modifications in technique of lumbar anaesthesia, and states that using the older methods he has had two deaths only and three cases causing serious alarm among a series of 5,000 cases. He excludes children under sixteen; pregnant women nearing term; cardiopathic subjects, and those with very low blood pressure, disease of the central nervous system, migraine, or sepsis; and azotaemic and dehydrated tuberculous patients, or those with recent syphilis. This author states that absolutely fresh solution must be used, the needle being free from soda or antiseptics. The injection must be made very slowly in the horizontal posture with the head at first raised, the pelvis not being raised for five minutes. When the blood pressure is low preliminary vasopressor injections are given. This method is regarded as free from danger for low abdominal operations—below the navel, with injection between the second and third lumbar vertebrae. For higher operations the technique is not as yet fully perfected, and Philopowicz points out that the special low position of the head which has to be maintained during and after the injection of air and low-gravity solutions (as in Kirschner's technique) is inconvenient to the patient and may be dangerous to the lungs.

Obstetrics and Gynaecology

225 Rupture of the Liver in the Newborn

EVA HOLMBERG (*Finska Läkarsällskapet's Handlingar*, November, 1933, p. 1067) notes that, before 1918, when Hedén published in a Swedish journal his paper on fatal injuries to the abdominal organs in the newborn, no systematic study had been made of rupture of the liver, and it was not realized that this accident might follow a normal labour. Among over 1,000 necropsies he found only two cases in which the liver had been ruptured during birth. The present author's material comes from a maternity hospital in Helsingfors where, in the period 1924-32, over 1,000 necropsies were performed. Among them were three cases of rupture of the liver in infants born at term and seven cases of such rupture in infants born before term. There were also nine cases of rupture of the liver occurring so long before term that the weight of the foetus in every case was under 1,000 grams. Among the infants born at term were two living at birth after the spontaneous completion of labour; in the third case forceps had been used. There is no reason to suppose that the mechanism of liver rupture in such cases differs from that of adults subjected to compression or flexion involving the liver. In both infants and adults a trauma is necessary. In the case of birth injuries pressure against the symphysis is probably responsible for the lesion, which is more likely to occur in premature than mature infants because of the comparative vulnerability of the tissues of the former. Asphyxia would seem to be a predisposing factor; it had existed in practically all the cases in which the infants were premature. Another predisposing factor is a tendency to bleed verging on the pathological.

226 Alcohol Lavage in Puerperal Infections

M. ROCH (*Zentralbl. f. Gynäk.*, December 2nd, 1933, p. 2860) states that Elgart still prefers 10 per cent. alcohol to Dakin's solution for intrauterine lavage, and has used it with good results in ninety-four cases. Besides its mechanical and bactericidal effects, the alcohol induces prolonged local hyperaemia and has an important general stimulant action. The corrected mortality in the series of cases quoted was 6.6 per cent.; the treatment was used in pyrexia with rigors after labour, or after abortions in which curettage had been ineffective. About 250 c.cm. of the solution was given four or five times daily through a rigid tube stitched to the cervix.

Pathology

227 Limited Diagnostic Value of Subcutaneous Injections of Tuberculin

N. LINDBERG (*Hygiea*, November 30th and December 15th, 1933, pp. 887 and 925) has analysed the findings in 260 obscure cases given subcutaneous injections of tuberculin (A.T.) in a Swedish sanatorium in the period 1916-25. This test was limited to those cases in which the diagnosis of active pulmonary or hilus tuberculosis was doubtful. As a rule, the initial dose was 0.5 or 1 mg. for adults. If there was no reaction after at least two days, this dose was doubled or trebled. In most cases the maximum dose was 8 or 10 mg. The temperature was taken every two or three hours after an injection. In 139 cases it was possible to ascertain the subsequent fate of these persons, sixty-six of whom had been negative while seventy-three had been positive reactors. On re-examination in 1932, as many as fifty of the negative reactors were found to be well. There were, however, eleven who had subsequently contracted tuberculosis, of whom seven had died of it. There were also five deaths among the negative reactors from diseases other than tuberculosis. What was particularly significant was that five of the negative reactors had developed definite signs of tuber-

culosis within a year of the test. It is generally considered to be impossible from a positive von Pirquet or Mantoux test to draw any conclusions as to the activity of the sensitizing lesion. A sharp febrile reaction after the subcutaneous injection of tuberculin is, however, held by some workers to indicate the presence of actively spreading disease. From his findings the author lays stress also on the value of a negative subcutaneous test in the exclusion of active tuberculosis.

228 Bacteriology of the Stool in Anaemia

K. FELLINGER (*Wien. klin. Woch.*, November 17th, 1933, p. 1380) has investigated the bacteriology of the stools in fifty cases of Addisonian pernicious anaemia, nine cases of post-haemorrhagic anaemia, eighteen cases of anaemia of various types, twenty-four cases of achylia gastrica without anaemia, and twenty healthy controls. Aerobic cultures showed no marked difference between the groups; haemolytic *B. coli* were grown from 18 per cent. of the cases of Addisonian anaemia and from 20 per cent. of healthy controls; from two cases of Addisonian anaemia a haemolytic *B. proteus* was obtained. Anaerobic culture showed that the stools of cases of Addisonian pernicious anaemia have a great increase of anaerobes compared with those of all the other groups. This increase affected particularly the content of *C. welchii*. Treatment with liver caused a diminution in the numbers of the latter, but never a return to the level shown by the controls. This increase appears unrelated to the cases of achylia, as cases of achylia without anaemia showed no such change. Investigation showed no constant variation of the amount of haemolytic toxin in the stools.

229 Early Diagnosis of Whooping-cough

M. DÉNES and L. LACÓR (*Orvosi Hetilap*, November 18th, 1933, p. 1049) have examined the characteristic changes occurring in the blood of whooping-cough patients with a view to facilitating diagnosis in the earliest (catarrhal) stage—when transmission usually takes place, when therapy is likely to prove most effective, and when, consequently, an early diagnosis is of the greatest importance. Sixty-five patients between the ages of 10 weeks and 15 years were examined with the following results: the blood in whooping-cough shows a moderate lymphocytosis coupled with a decrease of the sedimentation rate, absolute in the case of infants and relative in the case of children of more advanced age. A suspicious cough may, it is stated, be safely diagnosed as pertussis if the number of lymphocytes exceeds 10,000 and the sedimentation rate is normal or subnormal. Complications accompanying whooping-cough cause a slight increase in the granulated elements and an increased sedimentation rate in the blood. The authors conclude that, in the initial stage of whooping-cough as well as in doubtful cases, the blood count and sedimentation test constitute a valuable aid towards a sure diagnosis.

230 Blood Constituents in Myxoedema

I. ORNSTEIN (*Bull. Soc. Roum. de Neurol., Psychiat., Psychol. et Endocrinol.*, Nos. 1-2, p. 44) reports the results of the analyses of the blood in twelve cases of myxoedema, the B.M.R. values varying from -11 per cent. to -34 per cent. Total serum protein varied with normal limits, 7.29 to 8.3 per cent.; serum albumin and globulin also were within the normal range, and the non-protein nitrogen was between 20 and 29 mg. per cent. This confirms the findings of several other workers. Analysis of the serum fats and lipoids gave suggestive deviations from the normal. Total lipoids in this series lay between 0.73 and 1.15 grams per cent. (normal range 0.5 to 0.75 gram per cent.); fatty acids lay between 0.59 and 0.96 gram per cent. (normal range 0.35 to 0.60 gram per cent.); serum cholesterol varied from 140 to 193 mg. per cent. (normal range 150 to 170 mg. per cent.). The author takes his results to indicate a definite abnormality of fat metabolism. Details are not given as to the state of digestion of the patients.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

231 Post-vaccinal Encephalitis

As the result of a review of the occurrence of post-vaccinal encephalitis in Holland, E. GORTER (*Journ. Amer. Med. Assoc.*, December 9th, 1933, p. 1871) concludes that the irregularities in the distribution of cases are due to local and seasonal influences, or result from the use of a more dangerous vaccine during the months, and in the regions, of highest incidence. In favour of the first hypothesis is the fact that cases of encephalitis have developed following the use of vaccines imported from other countries. On the other hand, the predominance of cases during March supports the view that lack of sunshine plays a part, a view that has obtained some laboratory confirmation. Experiments seemed to indicate a relation between pigmentation and severe infections or complications. It appears certain, however, that some strains of vaccine have a greater liability to provoke encephalitis than others, sometimes owing to the association in the vaccine of living staphylococci. Gorter inclines to the view that post-vaccinal encephalitis is not comparable with herpes—due to a virus always present in the body and acting only when another disease has prepared the soil—but is rather to be compared with the nephritis complicating scarlet fever. Like many other complications, encephalitis can follow several infections—for example, measles—and the lesions found in this form of the disease are very like those of the post-vaccinal type. An objection is that vaccinal virus is hardly ever found in the cerebro-spinal fluid in post-vaccinal encephalitis, but a corresponding absence has been noted in cases of tetanus and diphtheria. Moreover, Herzfeld succeeded in tracing vaccine virus in the spinal fluid of some encephalitic children; in the Dutch cases it was not found.

232 A Sign in Appendicitis

H. SCHMORELL (*Zentralbl. f. Chir.*, December 2nd, 1933, p. 2792) has found a sign described by Carl useful in diagnosis of acute and chronic appendicitis. When palpation with the patient lying on his back gives no certain evidence of tenderness or rigidity, both may be demonstrated when he lies on the left side with flexed thighs and knees and pressure is made in a medial and backward direction over McBurney's point. The test is said to be invariably negative in acute adnexal inflammation.

233 Subphrenic Abscess

P. TRUESDALE (*Ann. of Surg.*, November, 1933, p. 846) discusses the various avenues by which infection reaches the diaphragm to cause a subphrenic abscess, and is of the opinion that the most common channel is by way of the lymphatics. Twelve cases of subphrenic abscess are reported, eight of which occurred in men and four in women. In seven cases the focus of infection was inside the peritoneal cavity, in one case within the thorax, and in the remaining four the history was suggestive of an intestinal lesion. Four of the intraperitoneal cases followed operation for appendiceal abscess. As so many cases developed after appendicitis, a study was made of the course of the lymphatics from the appendix to the region round the diaphragm. The bacillus-laden lymph passes from the appendiceal abscess to the appendicular nodes, which communicate with the ileo-caecal nodes, and from there to the lymphatic trunk following the superior mesenteric vein, which empties into the portal vein. A focus of infection at any point in the descending colon would gain access to these lymph channels. The lymphatics draining the entire colon reach the liver in juxtaposition with the mesenteric veins. This explains the frequent extension of malignant disease from the colon to the liver. The lymphatic vessels which pass through

the diaphragm terminate in the lower nodes of the inferior deep cervical group, and provide a direct route for the metastasis of the supraclavicular nodes induced by abdominal carcinomata. After coursing through the liver the lymphatic vessels finally reach the diaphragm with their infected lymph. Infection localizes above the liver and an abscess develops. The operative mortality in subphrenic abscess is very high. In the series reported it was 70 per cent.

234 A New Diagnostic Method

W. v. BREHMER (*Med. Welt*, December 9th, 1933, p. 1737) describes a new diagnostic method based on measurement of the hydrogen-ion concentration of the blood. The author designed a special apparatus for measuring, electrometrically, the hydrogen potential of the blood in the circulation itself. In place of the hydrogen potential valves (pH) given for human blood in the textbooks, and denoting a slight alkalinity (7.30 to 7.40), Brehmer found in healthy individuals an average of 6.3 up to 14 years, 6.8 up to 24 years, 7.2 up to 40, 7.35 up to 60, and 7.6 and more after that. Thus in young healthy individuals the blood is slightly acid, progressing towards alkalinity with advancing age. Diabetes patients between 45 and 68 showed pH values ranging from 6.6 to 6.9. Gastric ulcers gave two distinct sets of values: one from 5.94 to 6.37 and the other from 7.7 to 8.18. The author maintains that the latter were incipient cancer cases. Pernicious anaemia went with acidosis (pH values 5.9 to 6.98). Syphilis, in the tertiary stage, showed alkalosis with an average pH value of 7.65. Non-treated cancer cases all had values above 7.6. Brehmer believes that alkalosis of the blood is a *conditio sine qua non* of the development of cancer. X-ray or radium treatment shifts the index towards acidosis, the change persisting about two to three months. In no case could cancer be found within the range of pH values reaching from 6.8 to 7.5 (called "neutral zone" by the author), and there were only very few within the range 6 to 6.8. With these latter exceptions all cases showed values above 7.6. Brehmer thinks that should clinical symptoms prove to be accompanied by alkalosis of the blood early recognition of the disease will be assured; he believes, moreover, that, by modifying the hydrogen potential, prophylactic and therapeutic results can be obtained.

Surgery

235 Dislocation of Acromio-Clavicular Joint

K. LASSEN (*Hospitalstidende*, December 7th, 1933, p. 1196) has conducted follow-up investigations in two groups of cases of acromio-clavicular dislocation: (1) those treated in hospital in Copenhagen in the period 1920-31, and (2) those dealt with by the sickness insurance scheme during the same period. Of thirty-one cases in the first group traced and re-examined only four had been operated on; the remaining twenty-seven had been treated only by immobilization or massage. On re-examination, only sixteen were quite symptom-free. The remaining fifteen still suffered from pain and limitation of movement. Many could not carry a weight on the injured shoulder. All the sixteen symptom-free patients and ten of the others were, however, still able to follow their former occupations. In practically every case x-ray changes in the joint were still demonstrable. Indeed, there were only two, both children, who, after three and ten years respectively, showed no x-ray changes. As for the four who had been operated on, two belonged to the symptom-free group, although the x-rays showed that the sutures had given way in both cases. In a third case with pain when the patient lay on the affected side, the x-rays again

showed that the suturing had given way. In the fourth case it had not done so, but pain and limitation of movement persisted. After dealing in detail with the fifty-two cases in the second group, the author discusses the comparative merits of conservative and operative treatment, and comes to the conclusion that, in spite of the tendency of sutures ultimately to give way, operative treatment is indicated when the dislocation is severe. The course to be followed is less obvious in the comparatively common cases with a displacement of only about 1 cm. The tendency in the author's hospital during the last few years is to prolong the period of immobilization, and at the same time to concentrate on reposition with the help of Sayre's sticking-plaster.

236

Gastrectomy

J. DUVAL (*Bull. et Mém. Soc. Nat. de Chir.*, December 23rd, 1933, p. 1507), advocating gastrectomy as an excellent operation, describes gastro-enterostomy as a palliative operation only and one of necessity rather than of choice. During the last five years gastrectomy, he states, been carried out with increasing frequency, and in 1933 the author has performed it twenty-seven times out of thirty-three cases. Out of a total number of sixty-five gastrectomies there were only three deaths—one due to an inhalation anaesthetic which has since been discarded and the other two to the giving way of the sutures owing to the weakness of the tissues. He believes that gastric lavage and vaccines are of doubtful pre-operative value, and it is in the perfection of operative technique that the safety of the operation is secured. Local anaesthesia is recommended, novocain 1 in 300 being used. A special type of forceps and clamp are used which lessen the danger of tearing the tissues and facilitate the suture of the duodenum and vessels. Gastrectomy proved successful in seven cases of pyloric stenosis, which comprised five cancers, one ulcer, and an adenoma of the pyloric mucosa. It is considered that gastro-enterostomy is in every respect an incomplete operation which gives a false security and cannot be compared, as regards results, with gastrectomy. Duval states that gastro-enterostomy should be performed only where the removal of the lesion is impossible or dangerous.

237

Post-operative Tetany

O. WINTERSTEIN (*Münch. med. Woch.*, December 22nd, 1933, p. 2007) reports on the results obtained in the treatment of post-operative tetany with a new preparation, "A.T.10," recommended by Holtz (German Surgical Congress, 1933), described by him as irradiated ergosterol and prepared by the firms I. G. Farben in Leverkusen and E. Merck in Darmstadt. The dose is dependent primarily on the blood calcium level, and necessitates frequent blood examinations. At the beginning of treatment large quantities of A.T.10 are administered until the calcium level rises to normal, after which it is maintained on this level by smaller doses. In cases with serious symptoms of acute tetany—especially violent spasms and psychic excitement—accompanying a low calcium level, the return of the latter to normal may be accelerated with advantage by intravenous administration of calcium and the intramuscular administration of parathormone Lilly. Winterstein describes six cases treated by him with weekly injections of 2 to 3 c.cm. A.T.10. In all these cases the preparation raised the blood calcium level within a few days. The patients treated included two chronic cases which had been suffering from tetany for eleven and twenty years respectively and had undergone parathyroid grafting without results. The effects of A.T.10 in these cases were striking. The experience gathered up to the present with this treatment of post-operative tetany is slight, but the author states that there is no doubt that excellent immediate results can be obtained by it. It is, however, imperative to keep the blood calcium level under constant observation. Possibly the grafting of parathyroid might also give better results if a normal blood calcium level were first restored through the effect of A.T.10. Winterstein proposes to investigate this problem.

Therapeutics

238

Medical Treatment of Ureteric Stone

H. GISSEL (*Klin. Woch.*, December 2nd, 1933, p. 1867) mentions a series of ninety cases of stone in the ureter in eighty-five of which spontaneous expulsion occurred; administration of glycerin in combination with external hydrotherapy was part of the routine treatment. Small oxalate stones especially seemed to be promptly voided. Although organic and inorganic calcium salts (in contrast with uric acid and its salts) are much more soluble in glycerin than water, Gissel ascribes the effect of the glycerin, which was given in doses of 200 grams in one litre of sweetened water, chiefly to its diuretic action. Observations in men showed that after ingestion of 200 grams of glycerin the concentration in the urine did not exceed 6.2 per cent., with little alteration in viscosity. Haemoglobinuria has been reported after administration of considerably smaller amounts of glycerin in higher concentrations, but was not noted in this series.

239

Sodium Ricinoleate in Mucous Colitis

G. N. BURGER (*Journ. Lab. and Clin. Med.*, December, 1933, p. 234) records the result of treating twelve cases of irritable colon (mucous colitis) with sodium ricinoleate after they had failed to respond to a bland diet and antispasmodics. The doses ranged from 5 to 30 grains repeated four times daily. The drug was well tolerated by most of the patients, the few complaints relating to the large size of the capsules, occasional "sour belching," and a slight burning sensation in the epigastrium. The capsules were administered before meals and at bedtime. In most cases there was diminution of the pain and belching, and the amount of flatus was reduced in five, but no effect on constipation was noted. Mucus in the stools was appreciably lessened or disappeared in 50 per cent. of those patients who showed this symptom. Burger remarks that those patients who did not improve under this treatment had, with one exception, definite gastric symptoms after taking the drug. He concludes that this indicates the need of having a more adequate capsule coating, since the sodium ricinoleate, if liberated in the stomach and acted upon by the gastric secretions, gives rise to distressing symptoms. The skin sensitivity to organisms from the intestinal tract was materially reduced in nine out of ten cases; in two it was impossible to obtain sensitivity records at the end of the treatment.

240

Amidopyrine for Influenza in Infants

G. PETRÁNYI (*Amer. Journ. Dis. Child.*, December, 1933, p. 1011) has obtained good results from the administration of 3 or 4 per cent. solution of amidopyrine for influenza in infants and young children. The dosage was as follows: from birth to 1 month, 0.05 gram; from 3 to 6 months, 0.1 gram; from 6 to 12 months, 0.15 gram; and from 2 to 5 years, 0.2 gram. The temperature usually began to fall after the third or fourth day, and no unpleasant symptoms developed. The drug was continued two-hourly until the temperature reached normal, when the interval between the dose was increased to three hours, then to four hours, and later the drug was given only three times a day. When these doses were given to infants they bore the illness much better and lost less weight, while the other symptoms diminished or disappeared.

241

Insulin Treatment of Morphine Addiction

K. SCHAFFER (*Orvosi Hetilap*, December 16th, 1933, p. 1129) comments on the new method recommended by M. Sakel in 1931 for counteracting the disturbances resulting from the short-term cures of the morphine habit at present universally adopted in place of the gradual deprivation cures. The method consists in the administration of insulin, and has been applied by the author since 1932. Giving a detailed account of the first seven patients treated, the author states that in less serious cases, in which the cure is effected in three to five days, deprivation symptoms were eliminated by insulin with the greatest

case. In graver cases requiring cures of longer duration (eleven to fifteen days) symptoms were counteracted in an equally striking fashion. He states, however, that in some particularly serious cases insulin gave no favourable results or caused a severe hypoglycaemic reaction. One of the difficulties met with in the application of the method is the variability of the optimal dose, even in one and the same individual. The doses recommended are 15 to 20 units, which may be repeated in three to four hours' time, if found insufficient. The advantages of the method are the short duration of the cure, and the fact that patients take nourishment well from the second day onward and almost immediately begin to put on weight.

Dermatology

242

Loss of Hair

C. BRUHNS (*Deut. med. Woch.*, November 24th, 1933, p. 1751) describes in detail the various types of alopecia and divides them into two groups: (a) that associated with thinning of all the hair without the scalp showing any fibrous change, and (b) that associated with fibrous or atrophic changes in the scalp and usually, but not always, obviously the sequel of an inflammatory process. Alopecia pityroides is described as the most frequent form met with by the practitioner, and is due to hyperactivity of the dilated sebaceous glands. It occurs almost exclusively in men, and is variously called *seborrhoea sicca*, *pityriasis capitis*, and *alopecia furfuracea*. Hereditary tendencies to baldness are well seen in alopecia praematura, in which examination of the scalp shows a much greater loss of pointed hairs than is normal. In such cases anaemia, neuroses, endocrine disturbances, and general debility are not infrequent accompaniments, and *seborrhoea* may not be immediately obvious. In senile alopecia atrophic changes are demonstrable in the hair papillae, and there is a constriction and degeneration of the lymph spaces and capillaries. The same author (*ibid.*, December 1st) gives a useful review of treatment. Though no evidence of specific general stimulation of the growth of hair by means of internal medication has been obtained, he recommends iron, arsenic, and gland preparations. Local treatment directed towards hyperaemia and scalp stimulation includes high sun radiation and the use of the Kromayer lamp, administered until a mild erythema is produced. This is preferred to high-frequency currents, massage, and hot applications. In alopecia pityroides the following spirit application is recommended: resorcin 4 to 6 parts, acid. salicyl. 2 to 4 parts, ol. ricin. 1/4 to 2 parts (according to degree of *seborrhoea*), and 70 to 200 per cent. spirit. Euresol is used in preference to resorcin in blondes, while mixtures containing tincture of cantharides are also useful. Menthol should be added to the lotion (1/3 to 1/2 per cent.) for coincident pruritus. Other points mentioned by the author are: (1) the less frequent the washing, combing, and brushing in *seborrhoeic* cases the better; (2) treatment is relatively useless in pre-senile alopecia; (3) a useful stimulating preparation in alopecia areata is tinct. quin., tinct. cantharid., tinct. capsici, tinct. veratri, ã 10 parts, balsam. peruv. 1 part, and 70 to 200 per cent. spirit.

243

Chronic Paronychia due to Monilia

In thirteen cases of chronic paronychia IVAN CONNOR (*Med. Journ. of Australia*, September 2nd, 1933, p. 312) found that the causative organism was a monilia—*Monilia albicans*. All cases except one were in women. The infection caused minute abscesses under the nail fold which produced characteristic pad-like swellings of the fold itself, and on squeezing a small bead of pus could be expelled. The author states that the nail itself may sometimes be infected. Diagnosis was made by direct examination of material from the nail fold, which showed the usual appearance of chains and clumps of oval spores, and by culture on 1 per cent. glucose agar slopes, when filamentous and budding forms were also found. A com-

plement-fixation test was done in each case, but the results were not conclusive. The disease being a chronic one, Connor found in his series that the best results were obtained by keeping the hands scrupulously dry and applying monsol on a pointed match-stick into the pockets between the nail fold and the nail twice daily.

244

The Skin in Trichinosis

A. MUSGER (*Derm. Zeit.*, November, 1933, p. 34), who records an illustrative case, states that the dermatologist may sometimes be able to make the diagnosis of trichinosis from the skin changes, which are of a varied character, and constitute conditions such as urticaria, and morbilliform and scarlatiniform rashes, or may resemble the eruption of syphilis, typhoid, or typhus. They usually appear in the third week, shortly before the temperature has reached its height, and disappear in one to three weeks. During the febrile period miliaria, herpes, small haemorrhages, and pruritus may occur. Loss of hair may take place in convalescence. Musger's case was that of a woman, aged 34, who developed severe urticaria four days after eating a sausage, and subsequently the characteristic facial oedema, pains in the muscles, and eosinophilia (of 35 per cent.). The diagnosis of trichinosis was confirmed by finding trichinellae in an excised portion of the left deltoid. Recovery took place under the usual treatment.

245

Treatment of Staphylococcal Infections

J. I. CONNOR and M. McKIE (*Brit. Journ. Derm. and Syph.*, January, 1934, p. 20) record thirty-six cases of superficial staphylococcal infections in patients aged from 16 to 56, seventeen of which were examples of *syccosis barbae* and *syccosis nuchae*, and nineteen cases of carbuncles, boils, abscesses, and pustules, treated by injections of toxoid. In the cases of *syccosis staphylococcus* toxoid was used, and in the others crude toxoid. Complete cure or considerable improvement occurred in every case.

Obstetrics and Gynaecology

246

Pain Relief in Spontaneous Labour

L. McILROY and H. RODWAY (*Journ. Obstet. and Gynaecol. British Empire*, December, 1933, p. 1175) analyse 560 cases of spontaneous labour in respect of methods for alleviation of pain. Sedatives were used when uterine contractions occurred at about ten-minute intervals, corresponding generally with an os which admitted two fingers. Anaesthetics were given to primiparae throughout most of the second stage, and to multiparae when the head was about to be born. Most cases had potassium bromide and chloral hydrate ã grains xxx three-hourly to four-hourly to allay nervous excitability and prepare the way for stronger drugs. To avoid vomiting, the dose was given in glucose lemonade, and was sipped. Morphine was considered to be less dangerous and much more valuable than barbiturates or any other analgesic drugs; 1/6 to 1/4 grain was given hypodermically when sedatives became insufficient. Its effect was prolonged, sometimes intensified, by injection deep into the gluteal muscles of 2 c.cm. of a 50 per cent. solution of magnesium sulphate, two doses with a two-hour interval between. More often opiodine was used, either two tablets of 1/6 grain each by mouth, or, if distress called for more rapid relief, 1 c.cm. hypodermically—ampoules or a solution containing 1/3 grain per c.cm. Morphine administration proved to have good analgesic results in the majority of cases; to cause no alteration in the pains as a rule, though if they became less frequent they were also more effective; to give three to four hours' sleep or produce drowsiness in most cases; and to have no undesirable effect on the mother (except for rare idiosyncrasies). On the infant, careful inquiry showed no effect, even when morphine had been injected as late as half an hour before birth. The investigators state that prolonged slow or shallow respiration does not occur when CO₂ plus O₂ is used for resuscitation. Anaesthesia was

begun with 50 per cent. N_2O plus 20 per cent. O_2 , the latter being raised, if necessary, to secure the patient's co-operation. Administration started at the onset of each pain, and lasted for a half to three-quarters of a minute after its cessation. This anaesthetic increased the efficacy of the contractions in 50 per cent. of the cases; and enabled the patients to co-operate. The proportion of N_2O was gradually increased, and sometimes sufficed for delivery. More often chloroform was added for the birth of the head, both to ensure analgesia and to relax the perineum. As soon as the head was born, pure O_2 was given from Boyle's apparatus until the cord had been ligated. Used in these minimal doses, neither chloroform nor ether affected the child adversely. No case of post-partum haemorrhage occurred.

247 Rapid Biological Test for Pregnancy

M. R. BECKER (*Zentralbl. f. Gynäk.*, December 30th, 1933, p. 3073) mentions some dozen workers who have had accurate results in diagnosis of pregnancy by use of the Friedmann-Schneider modification of the Aschheim-Zondek test: rabbits are used instead of mice, and the result is available in forty-eight hours. He tested the urine by the original as well as the quick method in 117 cases, and found the tests to give the same result in over 90 per cent. Cases in which the quick test was erroneously negative appeared explicable by the use of too young animals. There were only two cases in which the original test was negative and the quick test rightly positive: in the first, only one of the five test mice survived; in the other the gestation was probably too early for diagnosis by the original test. There were five cases in which a very early pathological or aborting pregnancy gave a positive quick result but an Aschheim-Zondek reaction which was negative with Grade I phenomena.

248 Aschheim-Zondek Test in Pregnancy and Puerperium

Relying completely on the Aschheim-Zondek test as modified by himself, GARCÍA ORCOYEN (*Crónica Médica*, November 15th, 1933, p. 845) calls attention to the value of a positive reaction during the first ten or twelve days of the puerperium as evidence of recent delivery, though he notes its increased intensity in cases of molar pregnancy and chorion epithelioma. For the test he uses both young white rats and young white mice, agreeing with Brohna that the enormous development of the vesiculæ seminales which follows subcutaneous injection of the hormones of the anterior pituitary lobe is of equal value with the ovarian changes noted in young female white rats and mice similarly treated. He reports successful diagnosis of pregnancy as early as one week after the appearance of the catamenia. The technique which he describes is quite within reach of anyone conversant with simple histological methods.

Pathology

249 The Herpes Encephalitis Problem

F. P. GAY and MARGARET HOLDEN (*Journ. Infect. Dis.*, November-December, 1933, p. 287) discuss the origin of epidemic (lethargic) encephalitis, and bring additional evidence that it is due to a modified or adapted neurotropic strain of the virus of herpes simplex. In favour of the herpetic origin of the disease they advance the following arguments: (1) Herpes virus produces in many animals, such as rabbits and guinea-pigs, skin and brain infections that resemble respectively herpes and epidemic encephalitis in man. (2) In rabbits it can be shown that immunologically identical strains of herpes virus vary in their relative dermatotropic and neurotropic tendencies. (3) A subacute disease clinically resembling human encephalitis has been reproduced in *cebus* monkeys by the inoculation of herpes virus, and perivascular cuffing has been found histologically in the more prolonged experimental infections in these animals. (4) There is evidence in man that the naturally occurring antibodies active against the herpes virus suffer fluctuations both in herpes

and in encephalitis, suggesting a causal relationship of this virus to both diseases. (5) Both herpes simplex and epidemic encephalitis belong to the exceptional group of virus diseases in which recovery does not give rise to protection. The failure of many workers to isolate a strain of herpes virus from human cases of encephalitis may possibly be due to the lack of a neurotropic potency of the virus for animals. In illustration of this the authors refer to three cases of encephalitis following measles in which a virus was isolated that produced typical herpetic lesions when inoculated intradermally into rabbits, but failed to cause encephalitis on intracerebral inoculation. An additional case of encephalitis is described in the present paper occurring in a laboratory worker after a monkey-bite. A strain of herpes virus was isolated from the brain and cord that was fatal to rabbits inoculated either intradermally or intracerebrally and that produced a typical syndrome in *cebus* monkeys, while being relatively non-pathogenic for *rhesus* monkeys—a characteristic of the herpes virus. Cross-immunity tests, moreover, revealed the identity of this strain with a known strain of herpes virus.

250 A Modified Bordet-Wassermann Test

R. DEMANCHE (*Presse Méd.*, January 10th, 1934, p. 44) describes a modified Bordet-Wassermann test, which is simpler than, and as specific as, the standard Kahn reaction, and which may also be used in complement fixations with microbic antigens, especially in the gonorrhoea. Four tubes are used in the test: the centre pair (2 and 3), each prepared with a different antigen, are for the test serum, and the end ones (1 and 4) for the control serum; at the end of each series two tubes for the antigens are added. The complement consists of the mixed sera of several guinea-pigs, preferably males; to this is added one and a half times its volume of hypertonic saline solution, and, at the time of testing, three times its volume of distilled water is added to the latter, thus forming an isotonic complement. Before distribution into the tubes, an equal volume of diluted antigen is added for the two tubes of the reaction and an equal volume of physiological saline for the two controls; these mixtures are respectively termed activated antigen and activated physiological saline. The antigen is a 1 in 10 alcoholic extract of powdered heart muscle; this is used both as it is and with the addition of 0.3 per cent. cholesterol; both are diluted to 1 in 50 with physiological saline. Sheep's red cells, washed in and diluted to 1 in 20 with physiological saline, are used. The haemolytic amoceptor is anti-sheep rabbit serum containing at least 100 haemolytic units. A mixture of equal parts (0.3 c.c.m. per tube) of complement and each antigen is made. Into each tube 0.05 c.c.m. of test serum (or 0.5 c.c.m. of cerebro-spinal fluid) is pipetted, and 0.6 c.c.m. of each of the activated antigens added to tubes 2 and 3, and 0.6 c.c.m. of the activated physiological saline to tubes 1 and 4. Fixation is carried out at room temperature for forty-five minutes. Two strengths of red cell emulsion are prepared; 0.6 c.c.m. of the weaker is added to tube 1 and 0.6 c.c.m. of the stronger to each of tubes 2, 3, and 4 and the two antigen controls. All the tubes are then placed in a water bath at 37°C. for thirty minutes. When the antigen controls and tube 4 (serum control) are completely haemolysed, tube 1 should show only a trace of haemolysis. Readings can be made by direct examination, doubtful reactions being exceptional.

251 Spontaneous Reversal of Wassermann Reaction

E. T. HOVERSON, G. W. MORROW, and R. O. HAWTHORNE (*Med. Journ. and Record*, December 20th, 1933, p. 449) record nine cases of general paralysis in which, without treatment, strong positive Wassermann reactions in the cerebro-spinal fluid changed to negative. The authors are satisfied that the original diagnosis was correct in each instance, the clinical symptoms being typical. The view is expressed that such an occurrence points to the need of further investigation of the possibility of reversal of the reaction in the spinal fluid, apart from that of any therapeutic measures.

252 Large Haemorrhages from Gastric and Duodenal Ulcers: A Survey

O. MOSSBERG (*Hygiea*, December 15th, 1933, p. 897) has investigated the 1,032 cases of gastric and duodenal ulcer treated in a Swedish hospital in the ten-year period 1922-31. In 559 of these cases there was no history of haemorrhage in hospital or at any time before admission to it. Among the remaining 473 cases there were 177 in which the site of the haemorrhage was located by the x rays, an operation, or a post-mortem examination. These cases were divided almost equally between the stomach and the duodenum. A classification of the cases of manifest haemorrhage according to the seasons of the year showed that only 25 per cent. occurred during the first four months, 32 per cent. during the next four months, and 43 per cent. during the last four months of the year. The author does not attempt to explain these seasonal fluctuations, but notes that Mattisson corroborates him. Among forty-six deaths from haemorrhage, as many as thirty-eight occurred after the age of 40. Most of these deaths were directly due to the haemorrhage, and only a few occurred after a week or two as a sequel to complications provoked by a lack of circulating fluid. Post-mortem examinations of thirty-five cases showed how apt the clinical findings are to be justified by a necropsy; in about half of these cases the fatal haemorrhage came from a recent ulcer. The mortality from haemorrhage represented 2.7 per cent. of all the cases and 9 per cent. of all those with manifest haemorrhage. With regard to operative treatment, the author considers it contraindicated when the haemorrhage is presumably due to an acute condition with no, or only a short, history of premonitory symptoms. But when a haemorrhage is preceded by a clinical history indicative of chronic ulceration, or when the position of an ulcer has been located before the haemorrhage set in, an operation may, he states, be undertaken, particularly if the patient is over 40 years of age.

253 An Indicator of the Mean Arterial Pressure

A. G. TETELBAUM, M. I. KRINSKY, and O. F. ROMANOWA (*Presse Méd.*, December 30th, 1933, p. 2111) maintain that, to obtain an exact knowledge of the arterial pressure and circulation in general, the mean pressure (not to be confused with the arithmetic mean of the maximal and minimal pressures) must be ascertained. This pressure presents, in contrast with the great systolic and diastolic lability, a marked stability which gives it the characters of a true physiological constant, analogous to other constants such as the temperature, the blood pH, etc. Vaquez and others consider the mean pressure as a capital factor in assuring the stability of the arterial output of the circulation. The great sensibility of the systolic pressure is, however, valuable in certain circumstances, as in the crises of angina pectoris, and in differentiating hypertension, etc. According to these authors, it is only by combining the results of both determinations that a correct estimation of the arterial pressure and its oscillations is obtained. Various methods of ascertaining the mean pressure are cited—those of Marey, of Potain, and the oscillometric methods of Vaquez, Gomez, and Gley, of Plech, and of Moritz and Tabora. Vries-Reiling has demonstrated that the venous pressure in a compressed limb never attains the level of the systolic. The present authors concur in this, and utilize this venous pressure to determine the mean pressure, employing a modified Moritz-Tabora technique, which is briefly described. Examinations have been made on ten patients free from cardiovascular disease, on eight with aortic insufficiency, and on six with hypertension. In the first group the

difference between the venous and systolic pressures varied from 15 to 25 mm. of mercury; in the second the difference was greater and oscillated between 40 and 60 mm.; in the third, the venous pressure being greatly raised, the difference was only 25 to 35 mm.—approximately that of the first group. That the venous pressure is an indicator of the mean arterial pressure is explained by the fact that the veins in a compressed limb are not pulsatile, and, the arterial and venous systems being connected by capillaries which do not permit a rapid free displacement of the blood in either direction, the capillaries in the compressed limb can only discharge the blood in one direction—namely, into the veins—at the level of the mean pressure in the arteries.

254 Recto-Abdominal Palpation

To differentiate the muscular "guarding" seen in cases of abdominal inflammatory conditions from that due to non-inflammatory reflexes, A. YÓDICE (*Semana Medica*, December 21st, 1933, p. 1998) uses the following simple technique. With the patient lying on his back, thighs at right angles to the belly, knees at right angles to the thighs and feet planted on the bed or couch, he palpates the rectum with one hand while the other is similarly employed with the abdominal wall below the umbilicus, more especially where the rigidity is manifest. The author considers the result to be positive for the existence of inflammatory trouble when the rigidity persists, and states that the manoeuvre differentiates between contraction arising from peritoneal infection and that produced by intestinal or uterine colic or irritation of peripheral nerves. Phantom tumours disappear, and are thus separated from real ones. He believes that rectal palpation produces a spinal and sympathetic reflex which modifies the rigidity.

Surgery

255 Indications for the Operative Treatment of Goitre

E. RANZI (*Wien. med. Woch.*, January 13th, 1934, p. 61) writing as a surgeon in charge of a university hospital discusses the numerous factors to be considered in the choice of treatment for each case of goitre. One of these factors is the risk of an operative or post-operative death. Between 1925 and 1929 he lost only one patient (from air embolism) among the 714 cases operated on for goitre. This embolism occurred after the completion of the operation, when the dressings had already been applied. The post-mortem examination showed a patent foramen ovale. All statistics show that the operation mortality is much higher for exophthalmic goitre than for ordinary goitre; in the author's hospital the mortality for 27 cases of exophthalmic goitre, operated on during the past sixteen years, was 7.4 per cent. In those obscure cases of exophthalmic goitre in which the thyroid is but very slightly enlarged, an operation should not be attempted. The slighter cases of exophthalmic goitre should also not be operated on but reserved for x-ray and medicine treatment. As for the moderate and severe cases operative treatment is indicated only when the patient can be carefully prepared in advance by rest, diet, and medicinal treatment including the exhibition of iodine under the control of the basal metabolism. When, in a severe case of exophthalmic goitre with a much raised basal metabolism, the patient does not improve under this preliminary treatment, but continues to show signs of serious cardiovascular disease, the operator would do well to hold his hand. In addition to giving his own

experiences, the author quotes extensively from the statistics of other surgeons to show what are approximately the risks and achievements of operative treatment, and how much the former have been reduced within the last few years by a more cautious selection of cases for operation and by prolonged preoperative treatment.

256 Aetiology of Mammary Cancer

According to F. E. ADAIR (*New York State Journ. Med.*, January 15th, 1934, p. 61) there is clinical and experimental evidence that partial or complete obstruction of the mammary duct between the acini and the nipple aperture is a factor of prime importance in the development of mammary cancer. Such blockage may be caused by a localized outgrowth of the duct epithelium, abnormally shaped or fibrosed nipples, scarring involving the ducts, cyst formation, or a plug of desiccated and desquamated lining cells. An inflammatory reaction ensues, followed by hyperplastic changes which gradually become malignant. Chemical analysis of the fluid expressed from such obstructed breasts revealed the presence of lactic and butyric acids, which the author considers to be the irritating factors responsible for the tissue reactions resulting in hypertrophy, precancerous changes, and ultimately cancer. He analyses a series of 200 mammary cancer cases and 100 controls. Only 8.5 per cent. of the cases of mammary cancer gave a normal nursing history or a history entirely free from the various developmental or accidental incidents leading to at least one, and sometimes more, of the various factors in impairment of mammary drainage. In this cancer group every third pregnancy ended in miscarriage or abortion, while in the 100 control cases of normal women there was only one miscarriage or abortion for every seven pregnancies, and the nursing was normal in 80 per cent. In a strain of laboratory mice it was found that 5 per cent. developed mammary cancer spontaneously, but when artificial stagnation of the breasts was induced cancer ensued in 87 per cent. While admitting that this aetiology has yet to be fully substantiated, the author considers that his findings are strongly suggestive, and that the avoidance of lactation may have serious after-effects on the mother.

257 Hydatid Cyst of the Lung

N. ALIVISATOS (*Bull. et Mém. Soc. Nat. de Chir.*, January 27th, 1934, p. 75) gives his observations in thirty-one cases of non-suppurative hydatid cyst of the lung and reports fully one case in which the cyst was of unusual size. It occurred in a girl of 18 who complained of slight pains on the right side of the chest, accompanied by a dry cough and expectoration of mucus. There was no haemoptysis and no crepitations. There was dullness on percussion of the chest. X rays showed a shadow the size of a melon in the right lung. Operation was carried out and disclosed a large hydatid cyst which occupied nearly the whole of the right lung. The cyst was completely removed, but a second operation was necessary to drain a serous effusion which delayed convalescence. After this the patient made a good recovery. In the series of thirty-one cases it was found that pain was the most common symptom, but haemoptysis was only present in thirteen instances. In the majority of cases eosinophilia was absent, and in the case reported it amounted to only 2 per cent. In all the cases the reaction of Weinberg and the intradermo-reaction of Casoni were practised, and it was considered that the former was of the utmost importance as an aid to diagnosis. It was found that this became negative forty-eight hours after operation. Treatment of these cysts should consist of an extensive thoracotomy followed by the opening and removal of the cyst. It was considered advisable to fix the lung to the thoracic wall before opening the parietal pleura to avoid a sudden pneumothorax. Drainage was not found necessary in cases of small cysts, but only where the lesion was extensive and a large cavity was left with consequent risk of infection.

Therapeutics

253 Treatment of Serum Sickness

B. N. ARVAY (*Thèse de Paris*, 1933, No. 593), who reports twenty-six illustrative cases in patients aged from 6 to 40, states that ingestion of ephedrine hydrochloride is a simple and effective method for the prevention of serum sickness. The drug should be given by mouth as follows: The first tablet should be administered an hour before injection of the serum, and similar tablets six-hourly until the fourteenth day. The dosage is 1 cg. for children aged from 1 to 4 years, 2 cg. for children aged from 4 to 9 years, and 3 cg. for older persons. Of fifty-five patients so treated, forty-six of whom were adults and nine children, twenty-seven (49.09 per cent.) showed no reaction at all, and twenty-eight (50.91 per cent.), of whom twenty-six were adults and two children, showed some reaction which was almost always mild.

259 Clinical Applications of the Ketogenic Diet

According to H. GAINSBOROUGH (*Practitioner*, January, 1934, p. 45) the employment of a diet low in carbohydrates and high in fat is a very useful therapeutic measure in the treatment of epilepsy, *B. coli* infection of the urinary tract, and of migraine. A condition of ketosis results from the failure of oxidation of certain fatty acids. This is very effective in the petit mal condition in children, which, as a rule, responds poorly to phenobarbitone and the bromides. Its continuation for a long time in children seems to have no ill effects, although pellagra has been recorded as a sequel when the protein intake was too low. While epileptic children generally do well on a ketogenic diet, the results in adults are less satisfactory. In urinary *B. coli* infections the diet acts by means of the bacteriostatic effect of β -hydroxybutyric acid in a strongly acid urine; this degree of acidity may have to be induced by the administration simultaneously of ammonium nitrate or chloride. Reports indicate that well over 50 per cent. of these cases are curable thus, even though of long standing. Similar benefit has also been obtained in the pyelitis of pregnancy. A series of cases of migraine were treated by a ketogenic diet. The resulting improvement was attributed to the effect of the low carbohydrate intake, the ensuring of active gall-bladder drainage by the high fat content, the possible diminution of the ingestion of proteins to which there was an allergic state, and the anaesthetic action of the keto-acids.

260 Ultra-violet Light in Treatment of Anaemic Blood

C. FEVERS (*Deut. med. Woch.*, December 29th, 1933, p. 1922) has for about two years investigated the action of ultra-violet light on the circulating and shed blood of experimental animals and patients. It was found in both that when whole blood was withdrawn and then reinjected into the donor, there was an average rise of about 5 per cent. in the number of the erythrocytes both in health and (in man) in secondary anaemias. No definite effect followed the exposure to ultra-violet light of blood still circulating but made to pass through a quartz tube interposed in the circulation of the animal examined. But when about 20 c.cm. of blood were withdrawn from a vein and mixed with a 5 per cent. solution of sodium citrate in the proportion of 1 to 4, and left for five to ten minutes in a Petri dish some 20 to 30 cm. from a source of ultra-violet light, the intramuscular reinjection of this blood was followed by a very considerable rise in the number of the erythrocytes—a much greater rise than when non-irradiated blood was reinjected. The same effect followed the reinjection of irradiated blood into a vein. When the number of erythrocytes was already normal the average rise was 0.7 million, and when the number of erythrocytes was originally low (secondary anaemias) the average rise was 1.2 millions. Control observations with patients given arsenic, iron, etc., or none of these remedies, showed figures much below those of the irradiated cases. Within half an hour of such an injection there was a definite increase in the

number of the erythrocytes, which reached its maximum in three to four hours. This maximum was maintained, with slight variations, for twenty-four to forty-eight hours. During the following three to five days the number of erythrocytes would fall. A second injection provoked a second rise, and in one case the number of erythrocytes was raised from 1.4 to 4.8 millions in the course of fourteen days, during which three injections were given. There was a corresponding improvement in the clinical picture. The author suggests that there is a hormone in the blood, probably in its corpuscular elements, which is activated by ultra-violet light in a way analogous to that in which cholesterolin is activated by ultra-violet light. The spleen would seem to play an important part, as spleenless patients responded to this treatment with practically no rise in the number of the erythrocytes.

Laryngology and Otology

261 Primary Malignant Tumours of the Trachea

Malignant tracheal tumours may be primary or secondary; the former only are discussed by E. BARATOUX (*Ann. d'Oto-laryngol.*, November, 1933, p. 1272), who records two cases. Though of rare occurrence, they, present, when contrasted with laryngeal tumours, a high incidence of malignancy. They occur more frequently in males than females, and usually between the ages of 35 and 65. Both epitheliomata and sarcomata occur, the latter more rarely; vegetating, infiltrated, mixed, and polypoid forms have been noted. Their usual site is the extremities (especially the lower) of the trachea. Their evolution is slow, the ganglia are rarely involved, and metastases are still more uncommon. Inward extension of the growth causes dyspnoea; external extension forwards is infrequent, owing to the cartilaginous rings, but posteriorly it compresses the oesophagus, and may even invade it. The recurrent laryngeal nerves are often involved, resulting in laryngeal paralysis. Pulmonary infection is common, but gangrene has never been noted. The aetiology of these tumours is unknown; embryonic rests, local irritations, and syphilis have been advanced as possible causes. At onset the growth presents no diagnostic symptoms; this latent phase may last two years. Dyspnoea is the first and most marked symptom, which is often accompanied by cough and expectoration. Voice changes, dysphagia, a special attitude, pain, and subcutaneous venous dilatation in the pectoral and cervical regions are less frequent signs. Various forms—dyspnoeic, dysphagic, etc.—occur; these must be differentiated from cardiac and other dyspnoeas and the dysphagia of oesophageal cancer. Diagnosis is always difficult, and entails indirect laryngoscopy, endoscopy, and biopsies. The prognosis is grave, especially with associated pulmonary infection. Treatment is preferably surgical, and consists of an extensive excision of the tumour, or partial or total resection of the trachea. Radium therapy has been abandoned, though deep radiotherapy has occasionally been beneficial.

262 Infections of the Oesophagus

H. P. MOSHER (*Arch. of Otolaryngol.*, November, 1933, p. 563), who has previously reported his conviction that cardiospasm is due to fibrosis of the terminal portion of the oesophagus caused by infection from contiguous organs, believes that this part of the alimentary canal can be infected from within and without, and is often involved thus in acute and chronic general diseases. Such infection is followed by fibrosis, as is the case elsewhere in the body, and therefore there is ample opportunity for the formation of strictures. Isolated areas of fibrosis may be detected in arteriosclerosis, while in infections of the blood stream the oesophagus may be affected even to the degree of ulceration. Pneumonia may set up an oesophagitis, and dilatation of the subepithelial blood vessels is almost constant in diseases such as cirrhosis of the liver, which impede the venous circulation. This disease and infection

of the gall-bladder are among the chief causes of oesophagitis, as has been shown by necropsies. Haemorrhage into the muscular layers extensive enough to disrupt them may occur when there is back pressure on the oesophageal vessels. Mosher thinks that the glands of the oesophagus, which are especially liable to infection, are probably the chief route by which the infecting agent from within travels. Various clinical cases are recorded in support of these views and practical notes are given on fluoroscopic and barium-bag examination. The typical finding in fibrosis of the terminal portion of the oesophagus is a fibrotic narrowing at the beginning of the crural canal. This is not shown by the examination with barium, but is clearly brought out by the barium striped bag.

263

Leaking Brain Abscess

Under this title D. McKENZIE (*Journ. Laryngol. and Otol.*, December, 1933, p. 797) discusses the spontaneous rupture and gradual discharge of a brain abscess internally or externally. He cites three cases of leakage into the meningeal spaces, in two of which recovery ensued. The third patient would also have recovered had it not been for the unsuspected existence of a second cerebellar abscess, which persisted after the first one had been drained. This type of case appears to be much more amenable to treatment than is the temporo-sphenoidal abscess, which tends to grow to a larger size, and to be quickly fatal after rupture. The author records a case of external leakage from a large temporo-sphenoidal abscess, in which sudden relief from pain followed the escape of a copious discharge through the wound of a mastoid operation. There were no signs of any intracranial complication until the supervision of meningitis, which proved fatal. Of thirteen collected cases of external leakage, the abscess occupied the temporo-sphenoidal lobe in ten, in one case the cerebellum, and in two the frontal lobe, following frontal sinusitis. McKenzie comments on various clinical and pathological characteristics. In most cases the pus travels by the route through which the infection entered the brain, the tissues there being devitalized already, and in some cases disintegrated. Relief afforded by leakage is rarely sufficient to neutralize the pressure effects of a brain abscess, or to keep its bulk from enlarging, or its infection of the brain from extending. Rupture into a ventricle may occur in spite of the coexistence of a leak. The time when operative intervention is indicated is often problematical. It is usually wise to restrict its site to the inflammatory zone.

Obstetrics and Gynaecology

264 Pregnancy and Pulmonary Tuberculosis

E. BOVIN (*Hygiea*, December 31st, 1933, p. 945) records observations made at two large maternity centres in Stockholm where since 1917 all the women attending them have been given an expert examination of the lungs with a view to early detection of tuberculosis. During the twelve-year period 1917-29 some 50,000 women were thus examined, and 2,500 were classed as definitely tuberculous or as suspects. In the former category there were 586 women who underwent 676 confinements, not including abortions. Of the 138 deaths among these 586 women, thirteen were not due to tuberculosis. The tuberculosis mortality during an observation period extending to fifteen years in the oldest cases was 21.3 per cent. The cases were classified in four categories according to the severity and activity of the disease. In the last three categories, representing the relatively benign forms of the disease, were 469 women who collectively provided no evidence in support of the teaching that the processes of reproduction favour the development of pulmonary tuberculosis. In the first category, in which the patient's disease was actively progressive and associated with fever, cavitation, haemoptyses, general debility, and, as a rule, tubercle bacilli in the sputum, the situation was very different. The tuberculosis mortality among the 117

women in this category was 88.9 per cent. Among these 117 were sixty-six multiparae, responsible for two to ten confinements each. A study of the 104 deaths from tuberculosis in this category showed that in fifty-two cases the beginning or progress of the disease had not synchronized with the pregnancy or the first year after it. Taken as a whole, these observations should be interpreted as a corrective to the old dogma that the processes of reproduction are necessarily injurious to the tuberculous. In the case of multiparae who are so because contraceptives fail, as with one of the author's patients who underwent eight confinements and died of her tuberculosis seventeen days after the last confinement, a sterilizing operation may be justifiable.

265 Quinine Hydrochloride and Urea in Pruritus Vulvae

H. VIGNES (*Bull. Soc. Franç. de Derm. et de Syph.*, November, 1933, p. 1429) describes a method that he has used for several years for treating pruritus vulvae by local infiltration of a solution of quinine hydrochloride and urea. This substance produces prolonged local anaesthesia. Many of his cases were severe and of long standing, and some of them had resisted all the other known methods of treatment. A 1 in 400 aqueous solution is employed, stronger solutions producing persistent fibrous infiltrations. As quinine hydrochloride has little power of diffusion, it must be injected into every part of the affected area. A fine needle is used, and the vulva and its folds are infiltrated millimetre by millimetre with the solution. Any spots that are missed may be dealt with a day or two later. The anaesthesia obtained lasts for about a month, and if necessary the process may be repeated. Often, however, this is not required, as the pruritic symptoms do not recur.

266 Hysterography in Metritis

E. FORGUE (*Paris Méd.*, December 16th, 1933, p. 496) points out that metritis occurring in the fundus uteri frequently persists at the top, or in the angles of the cavity. The former is the commonest position for placental remains, and the latter may be easily missed by a curette. The injection of lipiodol into the uterine cavity (not tubes) is without danger, and forms a useful new method of localizing a growth before curettage. The radiogram is diagnostic between a tumour and simple hyperplasia. Hysterography may also be of service in showing conditions which obstruct drainage, thus indicating the correct treatment—that is, by dilatation of the cervical canal, correction of retroversion, in application of glycerin tampons, etc. Forgue occasionally removes, by a cone-shaped incision, the portion of the fundus which is the seat of a chronic infection.

267 Placenta Praevia

Discussing the treatment of placenta praevia (other than cases in which simple rupture of the membranes suffices) WEYMEERSCH and SNOECK (*Le Scalpel*, December 30th, 1933, p. 1909) strongly confirm the opinion of Paucot and Reeb, that lower segment Caesarean section is the correct method of delivery. For artificial rupture of the membranes the labour must be in full swing, the canal practically taken up, and the os dilated to at least the size of a five-shilling piece, with only very slight haemorrhage. Foetal mortality in such cases under good conditions is given as 34.5 per cent. The practitioner, therefore, is urged to waste no time in sending to hospital (1) all cases with even mild haemorrhage for a second time during pregnancy, (2) all placenta praevia cases bleeding at term, or (3) at the onset of labour. It is stated that by this means complicated obstetrical procedures with their foetal mortality of 67.74 per cent. are avoided. The authors insist on the value of the low segment operation, whereby they claim to have reduced their own maternal morbidity from 61.53 per cent. to 22.22 per cent. They proceed, moreover, to deliver a case of placenta praevia by this technique if the progress of labour gives the least cause for anxiety.

Pathology

268 Sterility Induced by Injections of Spermatozoa

E. SLOTKIN (*Med. Journ. and Record*, December 6th, 1933, p. 400) reviews various reports of experiments designed to test the possibility of producing sterility in the female by injecting spermatozoa subcutaneously. He believes that if sufficient numbers of spermatozoa are thus injected into a female rat a sterility is produced; this is usually temporary, but may be permanent. The measure does not affect the sexual cycle of the animal, and, when the effects wear off, healthy young are born. The delay in pregnancy seems to be variable with the individual rat, while some require much larger doses than others. Slotkin thinks the effect may be produced biologically, a spermatoxic antibody developing and disappearing later. Direct evidence of this has not yet been obtained, but there seems to be no indication of any action on the female generative organs or on the mechanism of ovulation. There was no change in the behaviour of the rats, and no signs of anaphylaxis could be demonstrated.

269 Diagnostic Value of Sugar in the Cerebro-spinal Fluid

W. MASCHER (*Svenska Läkaresällskapets Handlingar*, vol. lix, No. 4, 1933, p. 233) has collected in this laborious study the scattered publications of other authors, and the investigations conducted during 1931 and 1932 at a Swedish hospital where 289 lumbar punctures on 133 cases were followed by sugar analyses. It was found to be immaterial whether the lumbar puncture was undertaken in the fasting state or not. While there seems to be no hard-and-fast limits within which the sugar content of the cerebro-spinal fluid can be called normal, the figures for most of the authors' findings in healthy persons were over 45 and under 75 mg. per cent. Within the same limits there were many pathological cases. The concentration of sugar in the cerebro-spinal fluid followed that of the blood, but both the rise and fall of the former were comparatively late. The figures for the cases of epilepsy were all within the normal limits, but the cases of meningitis gave, with only a few exceptions, unusually low figures. This finding proved of considerable value to the differential diagnosis, particularly in that between tuberculous meningitis and other ailments such as encephalitis. Thus, in one case the onset of the disease and the clinical picture were suggestive of encephalitis, but the low sugar content of the cerebro-spinal fluid seemed to point to tuberculous meningitis. This diagnosis was confirmed by the subsequent course of the case and by the post-mortem examination. In purulent meningitis this sign is of less diagnostic importance, as the cerebro-spinal fluid contains other signs indicative of the true state of affairs. The author is unable to attach any prognostic importance to fluctuations in the sugar content of the cerebro-spinal fluid, but he notes that, in purulent meningitis, the concentration of sugar is directly proportional to the number of cells in this fluid.

270 Tissue Culture from Cancer of the Cervix

P. CAFFIER (*Zentralbl. f. Gynäk.*, January 6th, 1934, p. 44) has studied the survival and extension of fragments of carcinoma of the cervix in culture *in vitro*, and has observed the effect of simultaneous culturing with fragments of embryonic heart. He finds that the neoplasm survives longer when the latter is present, that signs are notable of invasion both of the outgrowths and primary fragments of fibroblastic tissue by tumour cells, and that connective-tissue cells appear to act as a nutritive depot for these. Such experimental findings run counter to the suggestion that connective-tissue reaction is an important factor in cure of cancer of the cervix: they conform to the finding that the results of wide are better than those of subtotal hysterectomy, although the efficacy of vaginal total hysterectomy shows that the removal of neoplastic lymphatic glands in the extended abdominal operation is not of paramount importance.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

271 Asphyxial Subcutaneous Emphysema following Collapse Therapy

P. BOURGEOIS (*Presse Méd.*, December 9th, 1933, p. 1981), discussing this rare complication of collapse therapy, states that it is mainly caused by futile attempts at pneumothorax, and is almost always due to multiple old pleuritic adhesions. In most cases a pulmonary perforation is made through a pleural symphysis, thus creating a broncho-subpleural and subcutaneous channel which allows gaseous infiltration. The elasticity of the tissues generally suffices to close the small track of a trocar, and the condition only arises when a larger instrument is used, especially if the lung be infiltrated or sclerosed, and the pleura thickened and symphysized. The emphysema only becomes acute when the gas in the pleural cavity is increased by large and rapidly repeated reinfusions. The condition may also arise during a pleuroscopy, followed (or not) by section of the adhesions. Successive violent attacks of coughing cause extreme elevations of pressure of the broncho-alveolar air, thus producing progressive subpleural and subcutaneous infiltration. At the onset the condition is not alarming, but the oedema rapidly extends, and in two or three hours involves, in order, the neck, eyelids, face, shoulders and arms, forearms, thorax, and abdominal wall. The head becomes fixed, the face swollen, and the voice raucous. Marked crepitation is always present, and, finally, cyanosis and dyspnoea develop. If the condition is not relieved, death supervenes in two or three days. Various medicaments (morphine, etc., for the cough, oxygen inhalations, cardiotonics) are enumerated. In moderate cases a compressive dressing usually suffices to arrest the oedema. In rapidly developing asphyxial cases surgical intervention is essential. Various operations are briefly described—incisions in the neck, closing of the fistulous track, and deep incision along this track with tamponing of the wound to allow of free exit of the air bubbles.

272 Tonsillectomy in Kidney Disease

G. CASOLO (*Il Morgagni*, December 10th, 1933, p. 1523) records his observations on cases of focal infection of tonsillar origin which he classifies as follows: sixteen were examples of acute partial glomerulonephritis, in which tonsillectomy was followed by cure in fourteen and improvement in two; eight were cases of acute diffuse glomerulonephritis, of which five were cured and three improved after tonsillectomy; three were cases of nephrosis in which no change took place, and five were cases of acute articular rheumatism in which tonsillectomy did not prevent the development of recurrences. Casolo comes to the conclusion that tonsillectomy is indicated in all acute and chronic renal affections which can be attributed to a tonsillar focus. It is also advisable in those cases in which, though cure is impossible owing to the diffuse nature of the lesions, fresh focal infections can be prevented.

273 Paratyphoid Outbreak Traced to a Carrier

M. GUERDET and M. PARNET (*Arch. de Méd. et de Pharmacie Militaires*, December, 1933, p. 674) relate how, one summer morning, nine soldiers reported sick. All of them had suddenly fallen ill about 2 o'clock that morning with nausea, vomiting, diarrhoea, colic, headache, and pain in the lumbar region. Their temperatures ranged from 38° to 40° C. Next day the number of patients had risen to forty-four (out of a military unit of 150). With rest and dieting most of the patients were cured in forty-eight hours, but thirteen had to be admitted to hospital. On the arrival of a bacteriologist, only two of the patients

were still violently febrile (39° C.). Blood cultures in both these cases yielded bacilli conforming to the characteristics of the paratyphoid B. Hermetically preserved foods could not be held responsible, as some of the patients had not touched any; the only food of which all had partaken, and which was suspect, was a dish of haricot beans. They had been cooked on the morning of June 4th, and had been served cold for the midday meal on June 5th, the day before the first patients reported sick. Between the cooking and the serving of these beans the weather had been exceptionally hot, and the conditions for the growth of organisms on them had been most favourable. All the beans had disappeared, but not the three men who had cooked them. They were accordingly admitted to hospital for examination. After a calomel purge, stool cultures were taken. In two cases only *B. coli* and enterococci could be found, but from the stools of the third cook a bacillus was isolated showing properties identical with those of *B. paratyphosus* B. It transpired that, some five years earlier, this man had been febrile for a month, and that his ailment had been diagnosed as typhoid fever. Various tests identified the bacilli found in the stools of this cook with the bacilli found in the blood of two of his victims.

274 Mistaken Diagnoses of Pernicious Anaemia

A. NORGÅRD (*Hospitalstidende*, December 14th, 1933, p. 88) has studied the records of the Danish national sickness insurance scheme with special reference to the influence that the new liver and stomach treatment of pernicious anaemia has had on this disease. One striking effect of this treatment is the increased tendency for pernicious anaemia to be thought of and diagnosed, often incorrectly. Patients are promptly put on the new treatment without the diagnosis of pernicious anaemia having been based on a thorough clinical and laboratory examination. The treatment obscures the manifestations of the disease so that it is much more difficult to diagnose than at the outset. Consequently, many patients are given a treatment which, though prolonged and costly, does them little or no good. While much valuable liver and stomach extract is being wasted in this manner the partial failures of the new treatment in genuine cases of pernicious anaemia during the last few years must be traced to an inadequate dosage. The author analyses the mistakes made in 102 cases put on liver or stomach extract treatment in slapdash fashion. The diagnoses ultimately arrived at were anaemia achylia simplex in twenty-four cases, neurasthenia and hysteria in eleven, climacteric metrorrhagia in ten, dyspepsia and gastric ulcer in eight, aplastic anaemia in seven, cancer of the digestive tract in six, arteriosclerosis in six, the anaemia of pregnancy in five, operations on the stomach in five, Banti's disease in three, sprue also in three. To the remaining fourteen cases as many as twelve different diagnoses were allotted. The author admits that the diagnosis of pernicious anaemia is difficult for lack of any one pathognomonic sign. But it must be made by a painstaking clinical examination supplemented by special examinations of the blood and functions of the stomach before a lifelong treatment is instituted.

275 Acute Oedema of the Larynx in Measles

K. S. OLIVER and E. L. TURNER (*Journ. Amer. Med. Assoc.*, December 2nd, 1933, p. 1801), who report illustrative cases in boys aged 7 and 4 and a girl aged 3 years, state that acute oedema of the glottis is a rare complication of measles. It may become so severe as to necessitate tracheotomy, as in the writers' cases. In all three instances its onset was several days after appearance of the rash, and not in the prodromal stage as in most of the cases on record. The boys recovered and the girl died.

Surgery

276

Anucaine in Proctology

R. V. GORSCH (*Med. Record*, January 3rd, 1934, p. 35) commends the use of anucaine as an analgesic in painful conditions of the rectum and anus. This preparation consists of five parts each of benzocaine and phenmethyl, one part of butylaminobenzoate, and one-eighth part of basic procaine in sweet almond oil. It is particularly serviceable in anal fissures, the injection being made first into the tissues just lateral to the external sphincter, and then directly below the entire bed of the fissure. The best results are obtained when the drug is evenly distributed, and not pooled in the tissues. Relaxation of the sphincter apparatus usually follows quite promptly, and further examination is rendered possible, the sphincter being gently dilated. Any sentinel piles or hypertrophic skin tags can now be excised. Anucaine must always be injected into the subcutaneous or deeper tissues, since it is apt to cause sloughing when introduced into the skin. In pruritus ani such injections are effective in alleviation, but have no curative value. They permit the performance of minor surgical procedures, such as the removal of excessive thickened skin to promote drainage from the lower levels. Very good results were obtained by the author in the treatment of external thrombotic haemorrhoids by a single injection of anucaine below the pile swelling. The anaesthesia is said to last for a week or more, the pain and discomfort cease, and the clot may be absorbed in time. In operating on internal haemorrhoids anucaine was found to be a valuable anaesthetic, with or without additional novocain or butyn medication. Gorsch injected the drug with good results in several cases of coccygodynia, and prefers it to alcohol. He advises it also for sphincter spasm and scars in the anal canal. He has never encountered the complication of oil tumours or any permanent subsequent changes in the tissues after its use, except scarring.

277

Tumours of the Adrenal Medulla

W. F. SUERMONT (*Zentralbl. f. Chir.*, January 13th, 1934, p. 70) distinguishes between (1) tumours of the adrenal cortex, which occur chiefly in girls and cause obesity, virilism, and hirsutism, and (2) those of the medulla, which cause slight permanent rise of blood pressure, with paroxysms of further rise in blood pressure in which pallor, coldness of the extremities, alterations of sensation, and possibly glycosuria are present, and after which profuse sweating usually follows. He adds a fifth to the four reported cases of successful extirpation of a medullary tumour for the second-named syndrome. The patient was a man, aged 29, whose interval blood pressure was 150/115 mm., and whose pressure during daily attacks of fifteen minutes' duration was 325/200 mm. The right kidney was palpable, and radiography after abrodil injection pointed to a suprarenal tumour. This measured 10 by 7 by 5 cm., and was derived from chromaffin cells; adrenaline injections were necessary for the fall in blood pressure which was noted during the two days following its extraperitoneal removal.

278 Diagnostic Arthrotomy for Chronic Diseases of the Knee

A. LÄWEN (*Deut. med. Woch.*, January 5th, 1934, p. 14) finds that in spite of the number and importance of modern diagnostic tests it is still sometimes desirable to open a knee-joint and look inside. At the surgical hospital of the University of Königsberg during the period 1928-33 there were treated fifty-three cases in which the diagnosis of tuberculosis of the knee-joint was certain or possible. There was no history of trauma, and in most cases there was thickening of the capsule of the joint or an effusion into it. In fifteen of these cases, mostly adult, the clinical and x-ray evidence indicative of tuberculosis was so convincing that resection of the joint was performed forthwith. In three other cases in which

the diagnosis was not obvious an exploratory incision on the inner side of the patella was followed by a rapid histological examination of a strip of excised capsule in which tuberculous changes were found. In four other clinically obscure cases the same procedure led to the diagnosis of synovial tuberculosis, two of these cases being subsequently treated on conservative lines, while in the other two radical operations were performed. In as many as fourteen cases the exploratory arthrotomy excluded the diagnosis of tuberculosis, a considerable variety of other conditions being found. In nine of these cases the histological examination of the capsule of the joint showed a simple chronic synovitis. The author stipulates that three conditions must be fulfilled before an exploratory arthrotomy is undertaken: (1) all the other diagnostic tests must have been given a fair trial; (2) there must be a prospect of the patient receiving better treatment than before as a result of the operation; and (3) it must be performed under irreproachable aseptic conditions by an experienced surgeon familiar with the appearance of the interior of a normal knee-joint.

Therapeutics

279 Mercurial Poisoning from Clinical Thermometer Wounds

According to A. BORCHARD (*Zentralbl. f. Chir.*, December 23rd, 1933, p. 2930) accidental wounding of the hand—usually in nurses—by a clinical thermometer may lead to retention of mercury in the wound: toxic symptoms supervene four to seven days later, the gastro-intestinal symptoms being less pronounced than the general lassitude and headache. Even when the amount of mercury beneath the skin is small, and especially when it is finely divided, chronic poisoning with signs of visceral affection may follow, and in one case at least amputation of the finger has been necessary. Nurses should be told of the dangers of thermometer wounds, and warned not to try to express the quicksilver—this leads to its finer division. A radiogram should be made promptly, and if the metal is in fine spherules the area concerned should be excised as a whole, fine copper drains (on which any mercurial residues may form an amalgam) being then inserted. The sharp spoon should not be used. Individuals show much variation in susceptibility, and when the spherules are coarse expectant treatment may sometimes be adopted: prolonged control of the urine is necessary.

280 Medicinal Treatment of the Common Cold

H. S. DIEHL (*Journ. Amer. Med. Assoc.*, December 23rd, 1933, p. 2042) has studied the relative values of various drugs and drug combinations in the treatment of 1,039 cases of acute coryza, 262 cases of subacute or chronic colds, 114 cases of influenza, and fifty-three cases of acute pharyngitis. The only medicaments found useful in acute coryza were opium and certain alkaloids derived from it. Combinations of papaverine with codeine, dilaudid, or morphine were followed by definite improvement in 74 to 78 per cent. of the cases, the dosages used with these combinations seeming to be practically non-toxic. For general use a mixture of codeine and papaverine seemed to be the most desirable in view of the high percentage of good results obtained, the low toxicity, and the absence of risk of habit formation.* Morphine and dilaudid (dihydromorphinone hydrochloride) combined were nearly as efficacious, but each was definitely more toxic alone than when associated with papaverine. Codeine, papaverine, powdered opium, and the compound powder of ipecacuanha and opium were followed by definite improvement in 56 to 61 per cent. of cases, the toxicity decreasing in that order, and codeine proving practically as toxic

* The dosage of the codeine-papaverine prescription recommended for a patient weighing 150 pounds is: codeine 1/4 grain, papaverine 1/4 grain; one in the morning, one in the afternoon, and three at bed-time.

as morphine. Diehl found that the powder of ipecacuanha and opium, although of value in the treatment of acute colds, was no more beneficial than the same amount of opium without the ipecacuanha. Sodium bicarbonate, acetylsalicylic acid, and a combination of acetylsalicylic acid, acetphenetidin, and caffeine, gave little better results than the lactose tablet used as a control, each being followed by "definite improvement" in from 35 to 42 per cent. of cases. It seemed possible to shorten the course of colds by the codeine-papaverine or dilaudid-papaverine compounds. No medication could be shown to benefit subacute or chronic colds, or acute pharyngitis; morphine was tried unsuccessfully in influenza.

281 Appropriate Use of Digitalis and Analeptic Drugs

To demonstrate that digitalis and the camphor derivatives (cardiazol, hexetone, and especially coramine are cited) have their respective uses, E. FROMMEL (*Rev. Méd. de la Suisse Romande*, December 25th, 1933, p. 865) first reviews the pharmacodynamics of these drugs. Each possesses a cardiac and extracardiac action. Digitalis acts on both the cardiac muscular and excitomotor tissues; it increases the tonic and refractory phase of the heart, but lessens its conductivity. Its extracardiac action is evinced by bradycardia, due either to its action on the vagus nucleus or through the carotid sinus. Its action on the respiratory and vasomotor centres and the nervous system is stated to be nil. Its action is prolonged over several days, and the drug also possesses marked cumulative properties. The camphor derivatives exert a cardioplegic action on healthy hearts, but on those intoxicated by chloral, the barbiturates, chloroform, etc., they have an analeptic and tonic action. They are powerful excitants of the respiratory and vasomotor centres, and, by their action on the extracardiac nerves, tachycardia and increased conductivity and intracardiac irritability are produced. Their action, however, is only temporary, and they possess no cumulative property. Thus, digitalis and the camphor derivatives cannot be substituted for each other. The former is the medicament of choice in organic lesions, asystole, sinus tachycardia, etc., and the latter, preferably coramine, in all cases of vasomotor paralysis and of respiratory and cardiac failure. Digitalis is incontestably the therapy for chronic, organic, cardiac affections, while camphor derivatives are essentially a therapy of urgency in the crises of high pyrexias and grave intoxications. Frommel states that, owing to their pharmacodynamic synergy, these two forms of medication can be beneficially combined.

282 Anthrax Treated by Organic Arsenic

H. A. SPENCER (*Journ. Trop. Med. and Hyg.*, January 1st, 1934, p. 9) reports the successful treatment of human cases of anthrax by intravenous injections of novarsenobillon, or, in the case of young children, by injections of sodium cacodylate into the gluteal muscles, which proved equally effective. These procedures were adopted in outbreaks in Bechuanaland in places where the supply of anti-anthrax serum was not immediately available. Spencer has no doubt that the sterilizing effect of these arsenical injections is general and immediate; healing can be seen to be beginning on the day after the first injection, and only in the case of the milder and weaker preparations does a second injection appear to be necessary. Enlargement with tenderness of the lymphatic glands nearest to the ulcers was always present, and this rapidly cleared up after the injections. As a local dressing for the ulcers glycerin of borax was found to be very satisfactory.

283 Fluorides in Hyperthyroidism

I. GOLDBERG (*Semaná Médica*, December 28th, 1933, p. 2106), who claims to have been the introducer of the "fluor" treatment of Graves's disease in 1928, having published his results in 1930, states that this treatment has no contraindications, is devoid of all danger, and superior to operative measures. Goldberg employs

sodium fluoride intravenously, and gives 5 c.cm. of a 2 per cent. solution on alternate days. Orally he prescribes 2.5 cg. of the salt in pill form. After a few doses the malaise disappears, the pulse rate is reduced, weight rapidly increases, and the basal metabolic rate is lowered. Both exophthalmos and thyroid enlargement are slow to disappear, but ultimately are much reduced or become unnoticeable.

Ophthalmology

284 Vaccine and Non-Specific Protein Therapy in Iridocyclitis and Hypopyon Ulcers

PERCIVAL HAY (*Medical Forum*, October to December, 1933, p. 410) finds that many cases, after eliminating those due to syphilis, sinuses, tonsils, cholecystitis, endometritis, and pyelitis, are caused by the *Streptococcus salivarius*. Four strains can now be agglutinated. The initial dose of 5 millions is increased by 1 million weekly. A reaction characterized by an exacerbation of the symptoms, and by lassitude, headache, dental pain, and induration at the site of inoculation, calls for a reduction in the dose. Though autogenous vaccines give the best results, a stock vaccine is, it is stated, very helpful. In protein therapy, milk is allowed to stand for twenty-four hours and is then sterilized in a test tube for four minutes. For an adult, 3 c.cm. (1 c.cm. for a child) is given intramuscularly in the buttock daily. The dose is increased by 1 c.cm. until 10 c.cm. is being given. The reaction is gauged by the temperature. Hypopyon ulcer, ordinarily a very bad prognosis, reacts amazingly well, and good results are claimed for this form of treatment.

285 Primary Carcinoma of the Lachrymal Sac

K. T. A. HALBERTSMA (*Nederl. Tijdschr. v. Geneesk.*, November 18th, 1933, p. 5200) reports a personal case, which is the first to be recorded in Holland, of carcinoma of the lachrymal sac. He has collected five others from the literature, as compared with four cases of sarcoma and one of lymphoblastoma. Benign tumours of the lachrymal sac such as polypi, papillomata, fibromata, and lymphomata are much more frequent than malignant growths, but in rare instances may undergo malignant degeneration. Carcinoma of the lachrymal sac is characterized by its extraordinary malignancy and its liability to cause complications by invasion of the nasal sinuses. In Halbertsma's case, which occurred in a woman aged 68, localized necrosis took place and perforation of the orbito-nasal septum.

286 Variations in the Incidence of Eye Disease

S. WERNER (*Finska Läkarsällskapets Handlingar*, December, 1933, p. 1126) refers to investigations in an eye hospital in Helsingfors, conducted six years ago, which showed that, during a quarter of a century, while both phlyctenules and trachoma had continued to decrease, the latter showed no seasonal incidence, whereas phlyctenules were most common in the spring. Following upon this study, the present publication deals with an analysis of the 59,769 cases suffering from other diseases of the eyes, treated at the same hospital as in-patients or out-patients in the period 1912-26. The card system of classification depended on diagnoses, many of which were symptomatic rather than aetiological. Altogether twenty-three different ailments and anomalies of refraction were considered. In the period under review the attendances per year have doubled, but while some diseases have remained stationary, numerically, the incidence of others has greatly increased. The number of cases of each disease was expressed as a percentage of all the cases taken together. It was found that anomalies of refraction, including presbyopia, have become much more frequent, myopia having increased from 1.7 to 4.3 per cent. of all the cases, and presbyopia from 0.9 to 5.6 per cent.

These figures are, he believes, a measure of the effect of education and the growing tendency of the public to obtain their eye-glasses from doctors rather than from a watchmaker's shop or the market place. The incidence of hordeolum has slowly risen, while chronic conjunctivitis has remained at about 7 per cent. with a dip down to about 4 per cent. in 1918 and the four following years. The curve of gonorrhoeal conjunctivitis was remarkably flat until the last few years, during which it has shown a downward tendency. Parenchymatous keratitis has behaved in the same way, but optic neuritis showed a rise in the period 1917-20, which corresponded with a prohibition that fostered the consumption of intoxicants of exceptionally poisonous quality. In addition to these annual fluctuations, monthly fluctuations were observed in the case of certain diseases.

Obstetrics and Gynaecology

287 Cancer of the Uterus and Ovary

O. FRANKL (*Wien. med. Woch.*, December 9th, 1933, p. 1394) furnishes some original statistical data in an article devoted to the early diagnosis of cancer of the uterus. In his gynaecological hospital 415 cases of cancer of the cervix were operated on in the period 1921-7. As judged by the five-year post-operative test, a cure had been effected in 48 per cent. An even higher percentage of cures could be claimed among those cases in which the patient came very early to operation. Thus, among the twelve cases in which the diagnosis of cancer of the cervix could not be made by a macroscopical examination, but depended on a microscopical examination, there were as many as ten ranking still as cures after five years. Turning to the relative frequency of primary and secondary cancer of the ovary, Professor Frankl disagrees emphatically with the Frankfurt school, according to which most cases of cancer of the ovary are secondary. In the period 1921-7 he observed as many as 103 primary cases, there being only nine cases in which the disease of the ovary was metastatic. It may be objected that a gynaecological hospital does not often admit those cases of primary cancer of the stomach, intestines, liver, and pancreas which yield examples of secondary disease in the ovary. A more complete and reliable picture is therefore to be obtained from general post-mortem statistics. In the period under review the Pathological-Anatomical Institute of Vienna conducted 19,002 necropsies, among which there were 121 showing primary and only 48 showing metastatic cancer of the ovary. The primary seat of the disease in these metastatic cases was the stomach in twenty-eight, the intestines in six, the liver in two, the gall-bladder in nine, and the pancreas in three.

288 A New Treatment of Placenta Praevia

C. J. GAUSS (*Zentralbl. f. Gynäk.*, January 13th, 1934, p. 93) points out that in placenta praevia the outlook for the mother is much improved when operative delivery is avoidable and it is possible to stop the bleeding by compression of the placenta by the foetal head—that is, when rupture of the membranes effectually produces haemostatic uterine contractions. If this rupture is not thus effective, Gauss grasps the foetal scalp by a forceps which he has devised, and maintains traction by connecting it, over a system of pulleys, with a counterweight. The forceps has a pelvic curve and two blades which terminate in transverse, grooved, and toothed plates: the counterweight is a bottle which is filled with 600 to 1,200 grams of water, according to the pressure which is found necessary for the control of the bleeding. Gauss found the method effective in fifteen cases which were without maternal mortality; there were six foetal deaths, but three cases of central placenta praevia were included. To injure the foetal scalp by Gauss's instrument is unavoidable, even if it is ultimately less dangerous than version; but in point of fact the results of the injuries in the present series were of cosmetic importance only.

Pathology

289 Repair of Heart Muscle Damage: Diet Experiments

E. AGDUHR (*Uppsala Läkareför. Förhand.*, December, 1933, p. 65) gives the results of a histological and electrocardiographic investigation on the production and repair of damage to the heart muscle in white mice. The animals were fed on a deficient diet and given fish-oil emulsion for periods of three to five months: at the end of this time some were killed; controls were given an adequate diet. Sections showed extensive degeneration of the myocardial cells, with increase in the supporting fibrous tissue. Changes in the electrocardiogram indicating depression of conductivity in the heart—namely, an increase in the PR and QRS intervals—appeared as early as the eighteenth day of the experiment, and reached their maximum about six weeks later. This picture is said to be very characteristic of fish-oil damage. At the end of the dosing period the animals were given a full and adequate diet. This was continued for 200 days, when the animals were killed and examined. Changes indicating regeneration of heart muscle cells were seen in all cases, but they were much more marked in those animals which had been on a full diet in the healing period than in controls. In the process of regeneration amitotic division of some cells and hypertrophy of others were seen. There was a variable increase in the amount of fibrous tissue present. During the healing period serial electrocardiograms showed gradual restoration of conductivity, but the correspondence between anatomical changes and those of function is not exact: functional changes anticipate the anatomical ones in the period of damage and outlast them in the healing period. In one animal no trace of a muscular conducting tissue could be seen in the ventricular septum, yet the tracing did not indicate complete heart-block. Some nerve bundles in the septum were intact, and it is suggested that the impulse for contraction may be carried by these. The author's main conclusion is that repair of a badly damaged myocardium may occur, and be complete if a full diet is given.

290 The Cat in Diphtheria Transmission

E. B. BROOKS (*Amer. Journ. Dis. Child.*, December, 1933, p. 1338), as the result of experimental work, concludes that cats and kittens are not susceptible to diphtheria of the rhinopharynx or lungs. They did not react to the Schick test or to inoculation with virulent diphtheria bacilli. He believes, however, that cats may act as carriers of this disease, their fur rhinopharynx becoming the habitat of these organisms from one to four days after exposure to diphtheria. He has obtained some evidence, moreover, that cats which are suffering from infection of the pharynx with Vincent's fusiform bacilli and spirochaetes are more likely to harbour and carry diphtheria bacilli on the pharynx than are healthy cats. These animals are, nevertheless, susceptible to parenteral injections of diphtheria toxin, which may cause death, but this can be obviated by the administration of diphtheria antitoxin.

291 Ovarian Hormones and the Post-climacteric Endometrium

K. HÜBSCHER (*Zentralbl. f. Gynäk.*, December 2nd, 1933, p. 2844) recalls that Smith and Engle produced menstruation in a castrated ape by injection of follicular and then corpus luteum hormone; and that Kaufmann by similar measures induced menstrual bleeding in a woman aged 22, whose ovaries had been removed five years previously. Very large doses were used. In a woman aged 80, suffering from total prolapse, Hübscher proved the endometrium to be atrophic. After twenty daily injections each of 10,000 mouse units of follicular hormone, followed by five daily injections of "luteohormone" in doses of ten rabbit-units, the uterus, which had become enlarged to the size of the fist, bled; a second curetting showed the characteristic histological features of the secretory phase.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

292 Non-perforative Peritonitis in Enteric Fever

H. POUDEVIGNE (*Thèse de Paris*, 1933, No. 599), who records ten illustrative cases in patients aged from 6 to 43 years, one of which is original, states, that non-perforative peritonitis in enteric fever, though rare, does occur. It is most frequently found in severe attacks of typhoid or paratyphoid fever, but also occurs in other forms. The symptoms are the same as those of perforative peritonitis. The diagnosis is difficult, especially if the existence of typhoid or paratyphoid has not been suspected. The prognosis is grave, but less so than that of perforative peritonitis. Immediate operation is required, the progress greatly depending on the rapidity of the operation. If the condition is found to be due to typhoid fever a right lateral incision is made, the termination of the small intestine is explored, a caecal fistula is performed, and a drainage tube inserted. If, on the other hand, the presence of enteric fever is not established, a median exploratory incision should be made above the umbilicus, a drainage tube inserted into Douglas's pouch, and a caecal fistula made by a small right lateral incision. Of Poudevigne's ten cases, four recovered, two without operation, and six died, on three of whom laparotomy had been performed.

293 Treatment of Thrombophlebitic Oedema

With a view to determining whether there was any evidence that exposure to x rays was beneficial in acute thrombophlebitis L. M. ZIMMERMAN *et al.* (*Journ. Lab. and Clin. Med.*, December, 1933, p. 243) have tested the effects of salyrgan, the mercurial diuretic, and of x rays on dogs in which acute thrombophlebitic oedema had been produced by the injection of a concentrated tissue extract into the femoral vein. In each series the rate of the disappearance of the fluid was similar, and definitely more rapid than in cases which had not been so treated. The action of salyrgan was capable of explanation, but that of x rays was obscure. It is suggested that the treatment might possibly exert an influence on the lymphatic flow, or cause a breaking down of lymphocytes and leucocytes, with the liberation of proteolytic enzymes and the digesting of the protein-rich exudate, so that it was transformed into a more easily absorbable modification. Or, again, the radiation might result in an ionization of the tissue fluids, or have some action on the general mobilization of fluid in the body. It is concluded that it is not yet possible to decide between these possible mechanisms, more than one of which may be operative. Further clinical and experimental investigations are being conducted to determine the value, limitations, and possible dangers of x -ray treatment in acute thrombophlebitis.

294 Ayerza's Disease

M. SAMOVICI and J. SACK (*Arch. des Mal. du Cœur*, November, 1933, p. 685) put on record a case of Ayerza's disease. The patient, who had had syphilis ten years previously, began to experience cough and shortness of breath on effort at the age of 30. Gradually he became more cyanosed and lethargic, and when he came under observation at the age of 46 he was in a state of advanced congestive failure. Thereafter, by the usual remedies, his condition improved, but considerable cyanosis and dyspnoea remained. The respiration rate was 36, the rhythm normal, and the pulmonary second sound accentuated. The red blood cells numbered nearly nine millions; the Wassermann reaction was negative. The blood pressure was 160/120. X -ray examination showed prominence of the pulmonary artery and increased density

of the lung fields due to sclerosis and bronchial congestion; the right auricle and ventricle were enlarged, and the "hilar dance," characteristic of pulmonary insufficiency, was observed. The electrocardiogram showed right ventricular preponderance and enlargement of P-waves. On retinoscopy the engorged veins were seen to be constricted where they crossed the arteries. The authors discuss the problem of pathogenesis in this case; it is possible that chronic broncho-pulmonary disease was followed by a secondary sclerosis of the pulmonary artery, or that broncho-pulmonary syphilis was accompanied by obliterative disease of the pulmonary artery of the same aetiology. Escudero is quoted as stating that in secondary pulmonary sclerosis, dilatation of the right ventricle occurs, whereas hypertrophy is characteristic of true Ayerza's disease. In the case presented, the evidence of right ventricular hypertrophy, syphilitic infection, obliterative changes in the pulmonary artery, polycythaemia, and cyanosis combine to form the clinical picture characteristic of Ayerza's disease.

295 Nervous Complications of Varicella

D. CORDA (*Arch. Ital. de Ped. e Puericolt.*, January, 1934, p. 286) reviews the literature and records three examples of nervous complications in varicella. The first was that of a female infant, aged 21 months, who on the seventeenth day of disease developed symptoms of poliomyelitis in the right lower limb. Recovery took place in a fortnight. The second case was that of a girl, aged 3 years, who on the sixth day developed symptoms of cerebellar ataxia, which subsided in about three weeks. The third case occurred in a boy, aged 4, and was also complicated by nephritis. Symptoms of encephalitis developed on the sixth day and ended fatally. There was no necropsy, but Corda suggests the presence of a haemorrhagic cerebral lesion.

Surgery

296 Osteomyelitis of the Ilium

C. BADGLEY (*Arch. of Surg.*, January, 1934, p. 83) states that osteomyelitis of the ilium is a rare disease with a grave prognosis. A large number of those who survive the acute infection present severe lesions of the hip-joint, such as bony ankylosis, fibrous ankylosis, or pathological dislocation of the hip. There may also be a chronic suppurative osteomyelitis which may lead to amyloidosis, septicaemia, and death. Twenty-four cases are reported; of which twenty were instances of chronic osteomyelitis of the ilium in which palliative treatment had been unsuccessful. The lesion generally occurs before the period of complete fusion of the epiphyses, but although the usual age period is under 25, the youngest patient in the series was 20 months and the oldest 75 years. There were eighteen males and six females. The outstanding symptom is pain in the hip, frequently in the region of Scarpa's triangle, though it may be felt posteriorly and be referred along the sciatic nerve. Deformity is also noticeable with tenderness on palpation. In subacute cases there may be swelling in Scarpa's triangle with induration and oedema over the ilium. Treatment in cases of subacute or localized lesion should consist of incision, drainage, and removal of diseased bone, with, if necessary, localized resection of the involved area at a later date. This type of case is the most favourable. In the diffuse type of case early drainage alleviates the clinical symptoms and lessens the chance of septicaemia. Trephining of the ilium above the acetabulum is of great value in diagnosis in the early stages. Later, resection of the wing of the ilium to the supracotyloid is easily

carried out. In osteomyelitis of the diffuse type with extensive general infection the mortality rate is very high, and resection of the ilium gives the patient the best chance of recovery. Of the twenty-four cases reported, seventeen were completely cured and two died, and of the remainder four were improved but still had small discharging sinuses. One had a recurrence of infection three years after operation.

297 Congenital Talipes Equinovarus

F. CURTIS and F. MURO (*Journ. Bone and Joint Surg.*, January, 1934, p. 110) comment on the unfavourable results often obtained in the treatment of club-foot by means of tarsectomy. An operation is described which has been carried out for the last two and a half years. This is said to give a better functional result and shorten the period of disability. The operation was performed in fifty-one cases, sixty-nine feet being treated altogether. In the series there was no family history of a similar deformity in the parents, although in four instances a sister or brother had the same condition. In the majority of cases Steindler's operation was necessary before the decancellation, and the lengthening of the tendo Achillis after the decancellation. X-ray photographs after operation showed an alteration in the shape of the os calcis, astragalus, and cuboid, whilst the outer border of the foot was changed from a convex to a straight or concave surface. The joint spaces were well maintained between the bones treated, and there was no growth disturbance in the bones. End-results of the series showed normal appearance and good motion in sixty of the feet treated; in eight the result was fair, and in one poor. The youngest child treated was 1 year old and the oldest 9 years. The operation described consists of the decancellation of the os calcis, astragalus, and cuboid. All the cancellous bone is removed from the cuboid, but only the anterior portion from the os calcis and astragalus. The foot is forcibly overcorrected by manipulation with a Thomas's wrench. To correct the metatarsus varus and decrease the convexity of the outer border of the foot manipulation is done over a rectangular bar, though in certain cases the outer shell of the cortical bone of the cuboid and os calcis must be split vertically with scissors to allow collapse. The leg is placed in a plaster cast for three weeks, when a reapplication of plaster is made after further manipulation. Plaster casts are applied in the overcorrected position for four months, after which an inside upright and outside T-strap brace is applied and physiotherapy and muscle education begun.

298 Surgical Antisepsis by "Activized" Silver

W. KRUSE and M. FISCHER (*Munch. med. Woch.*, January 12th, 1934, p. 49) describe a new method of antisepsis which they have developed. They "activate" silver or silver-plated instruments by dipping them in a solution of sodium carbonate and sodium chloride connected with a storage or dry battery; under the influence of the electric current the oligodynamically inactive pure silver is transformed on its surface into silver carbonate or chloride—that is, "oligodynamically activized." The authors tested the antiseptic qualities of such instruments by placing them on agar-agar staphylococcus cultures, when a sterile area was formed around the place of contact. They claim that instruments treated by this simple process considerably lessen the danger of infection—for example, in wound probing, catheterization, the application of forceps, etc. Such activation can also be carried out with instruments remaining in the human body for any length of time, and the process can be repeated *in vivo* any number of times. The silver plating of instruments is less expensive than chromium plating. "Active" silver can also be used as a colloidal solution or a powder for the preparation of ointments, plasters, tinctures, etc. Hands rubbed with "active" silver powder are described as being turned into antiseptic instruments and surgical dressings, while silk and catgut are made antiseptic instead of only aseptic by impregnation with the same substance.

Therapeutics

299

Treatment of Hay Fever

K. HANSEN (*Deut. med. Woch.*, February 9th and 16th 1934, pp. 210 and 233) reports from his hospital in Lübeck his encouraging observations on the treatment of hay fever with a polyvalent extract of the pollens of the plants he has found most often responsible for hay fever in Germany. Here from 90 to 100 per cent. of the patients are sensitive to grass pollens, while only 10 to 20 per cent. are also sensitive to the products of the lime tree and the acacia. In 1932 the author treated 316 cases, among which he had to register only thirty as not benefiting from his prophylactic treatment. In 1933 his patients numbered 645, of whom 123 (19 per cent.) were rendered completely symptom-free, 370 (57.5 per cent.) benefited decidedly, 96 (15 per cent.) benefited moderately, and only 56 (8.5 per cent.) derived no benefit. Professor Hansen describes in detail the dosage and spacing of what he calls typical or standard treatment by subcutaneous injections. He also refers briefly to three variations from this standard, which include the "rush-desensitization" of Freeman. It is claimed that specific desensitization of pollen allergy can, by appropriate dosage, be effected in more than 75 per cent. of all cases; and that the proportion of failures, already below 10 per cent., can be still further reduced if attention is paid to all the complicating factors in each case.

300 Tobacco Addiction and its Treatment

R. HOFSTÄTTER (*Wien. med. Woch.*, January 20th, 1934, p. 95) considers smoking unnecessary and much more dangerous than addiction to tea, coffee, kola, sugar, etc., on account of the dangers of psychic addiction. According to this author the problem is therefore not so much one of treating isolated adults as of educating the younger generation of both sexes. With regard to the extraction of nicotine from tobacco, he states that while it is true that the August Falk method reduces the nicotine content of cigars and cigarettes by 40 to 50 per cent., it must be remembered that all are not agreed as to nicotine being the most dangerous constituent of tobacco. After discussing the various methods advocated for the gradual cure of the tobacco addict, the author expresses his scepticism about palliative measures, having confidence only in complete abstinence. Nearly all the married women and girls classed as nicotine addicts suffer, in his opinion, from ungratified sexual instincts, and their cure is a most difficult matter, which requires on the part of the physician much time, insight, and some psycho-analytic knowledge. The withdrawal of tobacco may not threaten the patient's bodily health, but her mental state may be seriously affected. The author has known the withdrawal of tobacco from women to be followed by serious mental symptoms, including a strong sense of guilt, fear, aggressive outbreaks against some harmless person, and a craving to masturbate. On two occasions sexual aggressiveness developed in relation to quite new and unsuitable objects. The withdrawal of tobacco may also promote a craving for alcohol or a narcotic. All these manifestations lead to the conclusion that the woman tobacco addict is nearly always neurotic and psychopathic, whose tobacco troubles are only one aspect of an abnormal constitution.

301

Medical Treatment of Bronchiectasis

GIRBAL (*Presse Méd.*, January 20th, 1934, p. 111) agrees with Sergeant that bronchial dilatation is a chronic affection with acute exacerbations, and that infection is the pathogenic basis of both the dilatation and the accompanying lesions and complications. This pathogeny should dominate and direct treatment. The infection can be carried by the blood and air passages. The former causes a dissecting peribronchitis, followed by hypergenesis and ending in a dense sclerosis—a true defensive reaction. Girbal does not concur in the opinion that syphilis is a frequent infective agent, but believes that descending

primary and secondary infections through the respiratory passages are primordial; these cause repeated lesions of broncho-alveolitis which terminate in peribronchial and pulmonary sclerosis. Pneumococci predominate as infective factors; streptococci and staphylococci, Pfeiffer's bacilli, anaerobic bacteria, etc., are concomitant organisms. Treatment (non-tuberculous cases are alone considered) should be directed to the infectious process and not to the sclerosis; the latter is desirable in isolating the suppurating bronchi from the enviroining parenchyma. In the chronic stage Girbal gives a series of six injections of pulmonary vaccine (*type amphi*); the initial dose of 0.2 c.cm. is progressively increased to 1 c.cm. for the last two doses. These are injected into the suprascapular region every four days; reaction should be noted, an interval of a day or two being allowed if necessary. The series is repeated every six to twelve months according to the patient's sensibility. Bacterial changes and diminution in the purulence and amount of the expectoration ensue. In acute crises small progressive doses (1/10 c.cm.) are given every four days, associated, except in cases of hepatic insufficiency, with intravenous injections of alcohol. With similar exceptions a series of ten alcoholic injections (1 in 5) is given bi-weekly, commencing with 10 c.cm., in non-febrile fetid forms. To restore pulmonary insufficiency caused by the dilatation, opotherapy is employed; a cachet containing 0.5 cg. of pulmonary extract is given orally before each meal five days monthly. Notes of a typical illustrative case are appended.

Radiology

302 X-Ray Treatment of Plantar Warts

E. T. LEDDY and E. JOHNSON (*Minnesota Med.*, September, 1933, p. 574) report 100 cases of plantar warts treated by x rays. The superficial layers were first pared off so as to render unnecessary high dosages and thick filters. The tissues surrounding the wart were protected by lead foil 1 mm. thick, and an opening punched in this gave access to the x rays. A mechanical rectifier and Coolidge tube were used. Low voltages of 80 and 100 PkV were most frequently employed without a filter, but higher voltages were tried for the rare large infiltrating lesions, an aluminium filter of 2 or 5 mm. being introduced. The focal skin distance was 9, 12, or 16 inches, the time of exposure being varied proportionately. The milliamperage was 5, 6, or 8. The total dose ranged from less than 2.3 to 5 skin erythema doses, this dose representing 375 r measured in air with no back scattering. With the lighter doses the treatment was repeated at intervals of one or two weeks on two or three occasions, but when the heavier doses were used the treatment was not repeated until after two months, and then only once, if indicated. Of the 100 cases cure resulted in seventy-six, a new wart followed cure in six, failure was recorded in eight, symptomatic benefit alone was present in four, and in six instances the result was uncertain. The authors conclude that this treatment must be regarded as effective. It is painless and leaves no scar. In 80 per cent. of cases a single application is adequate, but this must be of not less than 14 nor more than 34 unfiltered skin erythema doses. It should not be repeated until after two months, and if this fails some other treatment must be tried, for some warts seem to be peculiarly resistant to radiation.

303 Collapse of Lung and Atelectatic Bronchiectasis

M. DE BRUIN (*Nederl. Tijdschr. v. Geneesk.*, December 2nd, 1933, p. 5345), who records four illustrative cases in children aged from 2 to 8 years, states that x-ray examination sometimes shows a triangular shadow in the medial and lower part of the lung, which has hitherto been regarded as due to mediastinal pleurisy. A study of the literature, however, and his own observations have convinced the writer that this opinion should be revised. Although mediastinal pleurisy may produce this shadow it is often caused by collapse of the whole or part of the

lower lobe of the lung. De Bruin draws attention to the fact that such collapse may be associated with bronchiectasis in the atelectatic region of the lung. Collapse probably occurs first, bronchiectasis subsequently developing in the atelectatic lobe.

304

Oral Cholecystography

S. KADENKA and L. SECHEHAYE (*Journ. de Radiol. et d'Electrol.*, January, 1934, p. 21) state that the disadvantages of oral cholecystography can be obviated by employing colloidal forms of the iodine salt in divided doses, according to Sandstroem's method. Nissen reports as excellent results by this procedure as by the intravenous. The present authors record those in fifty-six cases, which confirm this finding. In this method the patient need not fast, but all cystokinetic and flatulent foods are prohibited for the last meal before the examination and throughout its duration. The last meal must not be large, and is taken at least three hours before giving the first dose of the salt. Preliminary purgation is unnecessary and undesirable. According to the patient's weight, 1.5 to 2 grams of iodine-tetragrost (Merck) are divided into three equal doses. Each is dissolved immediately before use in a spoonful of water; this is poured slowly into 200 to 400 c.cm. of alkaline gaseous water, such as Vichy, with constant stirring; fruit juice can be added to disguise the taste. These doses are given at twelve hours' interval, the first in the evening, the second the following morning, and the third that evening. To favour the pyloric passage of the salt the patient is placed in the right lateral decubitus. The radiograph is taken on the third morning after administration of an enema of warm water. Plates are taken with a Potter-Bucky apparatus in the ventral and upright positions and in profile. After the examination a purgative or enema is given to promote evacuation of the salt. Should immediate information be desired, Sandstroem gives a full dose (3 to 4 grams) in the evening and makes the examination the next morning after thirteen hours' interval; if results are negative a further dose of 2 to 3 grams is given. In the latter cases the present authors prefer to give the small divided doses, and immediately after the negative examination a second dose and in the evening a third, each of 1.5 to 2 grams. The harmful effects of the tetraiodide are markedly reduced by this procedure. In only six of the fifty-six cases were any noted; these consisted of an urticaria, vomiting, hepatic pains, and laxative effects.

305

Radiography of the Shoulder

J. N. FERGUSON (*Brit. Journ. Radiol.*, January, 1934, p. 33) suggests an improved technique for the radiological examination of the shoulder, the usual single antero-posterior view being supplemented by one more nearly lateral, with the scapula almost "edge on." The patient is placed on the Potter-Bucky diaphragm in the supine attitude in the first instance, and the sound shoulder is elevated by pads so as to cause rotation of the body through 30 or 40 degrees. The head, supported by a firm cushion, is turned sideways towards the damaged side, bringing the scapula forwards in relation to the body, and more nearly parallel with the film. (The curved type of Potter-Bucky diaphragm is specially suitable to this end.) The shoulder need not be kept in the middle, but may slide to one side into a position of stability. The oblique ray in this situation will be perpendicular to the scapula and pass along the plane of the glenoid margin, the film being suitably decentered. The patient is now helped to turn himself over, and to lie nearly prone with the sound shoulder elevated and the damaged one in contact with the diaphragm top, sliding a little to one side for stability. The scapula is now slightly inclined from the vertical, and in the path of the oblique ray. The author remarks that these two positions sound rather uncomfortable, but that most patients can manage them fairly well, slight degrees of maladjustment not affecting the diagnostic value of the resulting picture. Variations of the technique are possible for special requirements. In attaining the position desired the body weight aids the movement of the shoulder, a process well exemplified in

cases of damage to the acromio-clavicular joint. Fergusson adds that undoubtedly many cases of subluxation are missed when the examination is made with the body in the usual supine position.

Obstetrics and Gynaecology

306

Endometriosis

G. COTTE and A. TRILLAT (*La Gynéc.*, December, 1933, p. 641) point out that adenomyoma of the uterine wall is frequently mistaken for simple hyperplasia. There are two types of endometriosis of the fundus: (1) circumscribed, distinguishable from simple fibroma (only at operation) by the fact that there is no capsule, so that excision, not merely enucleation, is required; it contains "chocolate" cysts. (2) Diffuse—(a) localized and nodular, or (b) invading the whole organ and enlarging it up to the size of full-time pregnancy. This calls for hysterectomy. Its nature is evident from the microscopical finding of cystic spaces lined with ciliated cuboidal epithelium. The theory of origin preferred by this author is that of hyperplasia and invasion of the musculature by the endothelium, due to some chronic inflammatory influence. Symptoms are not typical, but may be suggestive. They are: (1) dysmenorrhoea, beginning with puberty or developing gradually—the pains are suprapubic, pelvic, and often expulsive, they begin before and continue throughout the period of the flow; and (2) metrorrhagia, not of distinctive onset, but parallel with the dysmenorrhoea and later becoming prolonged menorrhagia. The comparative regularity of outline in an adenomyomatous as compared with a fibroid corpus is a point in diagnosis. A difference in volume in the pre- and post-menstrual stages is said to be appreciable. In treatment, medical methods are ineffective. Neither menopause nor irradiation checks the growth. Hysterectomy is the rule, but there are exceptions. If the adnexa are healthy, excision of the tumour alone is sometimes possible. Supravaginal hysterectomy is allowable so long as the growth has not passed beyond the uterine walls. If it has, panhysterectomy is required.

307 Treatment of Occipito-posterior Presentation

Analysing 976 cases of occipito-posterior presentations, G. MELHADO (*Amer. Journ. Obstet. and Gynecol.*, November, 1933, p. 696) argues that subnormal formation of the pelvis does not account for all cases. Anterior position of the placenta, uneven development of the two Müllerian tracts, relaxed pelvic floor, inability of the trunk and shoulders to move forward, as well as inadequate flexion of the head, are all causes of persistent occipito-posterior presentations. The shoulders are commonly fixed by an internal contraction ring. To eliminate this and improve flexion the writer advises interference directly, following full dilatation, the head ceases to advance. His method is manual dilatation of the vagina and careful palpation of the head to make sure of the diagnosis, followed by dislodging the head upwards into the pelvic brim. If a contraction ring is forming it is ironed out. The anterior shoulder is found and pushed well forward. The head is then placed with the sagittal suture in the transverse diameter and the posterior ear lying in the operator's palm. Along this is passed the lower blade of the forceps, shorter curve facing the occiput, and fitted over the posterior ear. The upper blade is passed over the anterior ear and the pair locked. By gentle rotation the occiput is brought forward and the head into the oblique diameter. These manoeuvres are safe, because the head is free above the brim. When it is drawn into the brim again it descends with surprising ease, and is delivered. Criticism of the method is met by stating that neither prolapse of the hand or cord occurred in the series, and that operation above the brim, on a head that has previously descended into it, is quite a different matter to the application of high forceps to a head that had never entered it.

698 D

Pathology

308 Diagnosis of Mediterranean Fever

J. C. CARANZA (*La Med. Ibera*, January 13th, 1934, p. 33) who records sixteen illustrative cases in patients aged from 15 to 76, states that Burnet's intradermo-reaction is not absolutely specific for Mediterranean fever, as it may be positive in other conditions. The reaction is, however, always present and well marked in Mediterranean fever. The serum-agglutination test, on the other hand, is not constant. Lastly, leucopenia, lymphocytosis, and monocytosis are always present, so that the association of a positive intradermal reaction with the changes in the leucocytes mentioned is of considerable diagnostic value.

309 Active Immunity in Experimental Syphilis

W. KOELE and R. PRIGGE (*Med. Klinik*, January 12th 1934, p. 46) report an extensive series of experiments to ascertain whether it is possible to stimulate the development of active immunity against syphilis in rabbits. The animals were infected with either the Truffi or the Nichol strain of *Treponema pallidum*. Three to eight months later they were given three doses of neo-salvarsan. After a further six months they were superinfected, either with the homologous or the heterologous strain. Finally, six to eight months later, the lymph glands and testicles were excised and inoculated into normal rabbits to determine whether they contained living spirochaetes. Of twenty-seven animals superinfected with the homologous strain one developed a chancre, five showed secondary lesions while the remainder showed no clinical evidence of disease whatever. Yet in eighteen out of these twenty-one animals virulent spirochaetes were demonstrated by inoculation into fresh rabbits. Of twenty-six animals superinfected with the heterologous strain, eleven developed chancre and three secondary lesions. Of the remaining twelve rabbits, which showed no evidence of disease, eight were found to be harbouring living spirochaetes. In both series control syphilitic rabbits that had been treated with neo-salvarsan but not superinfected were found to be free from infection. In further experiments on eighty-nine rabbits the animals were left for nearly a year after the first infection, to give them time to develop immunity. They were then treated with neo-salvarsan. About a year later some of their glands were excised and tested for virulence. They were then superinfected with the homologous strain, and about nine months later the remaining glands were examined for infectivity to normal rabbits. In forty-seven animals given large doses of neo-salvarsan the glands on the first examination proved uniformly negative. None of these animals developed a chancre on superinfection, yet in seven out of twenty tested after superinfection virulent spirochaetes were demonstrated. From these experiments the authors conclude that though a chancre immunity may develop, an immunity of sufficient intensity to prevent reinvasion with fresh spirochaetes does not occur in experimental syphilis. The practical conclusion they draw is that syphilis should be treated as early as possible by chemotherapeutic agents.

310 Pathology of Pernicious Anaemia

J. BENGE (*Orvosi Hetilap*, January 6th, 1934, p. 1), discussing the part played by the stomach in the pathology of pernicious anaemia, defines the latter as a deficiency disease in the sense that some substance stimulating and regulating normal blood production is lacking. Believing that this substance has its origin in the gastric wall, and in support of this thesis, the author carried out a series of experiments, using liver extracts taken from gastrectomized hogs. Liver extracts taken from such animals proved ineffective in cases of pernicious anaemia, which promptly responded to treatment with normal liver extract. The author considers his results as conclusive proof of the gastric origin of the active principle in liver extracts.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

311 Lacquer-work Poisoning

M. ELLERMANN and J. JAKOBSEN (*Hospitalstidende*, December 14th, 1933, p. 1213) have inspected fifteen motor-car factories and workshops where "duco-lacquer" was sprayed on to surfaces through a compressed-air tube. Though most of the dissolved lacquer was deposited, as intended, on some surface, a considerable proportion of the fluid was suspended in droplets in the space about the worker, who thus came to be surrounded, when adequate ventilation was not provided, by a fog of colouring matter and of the substances used to dissolve it. The solvents of lacquer are almost numberless, and the composition of various preparations is apt to be kept a trade secret. Seventy-three workers in lacquer were asked a set of questions by the authors, who found that a fairly well defined clinical picture of acute or chronic poisoning was quite common. As many as fifty-five suffered from a sore throat, fifty from irritation of the nose, and forty-two from smarting of the eyes. There were forty-seven confessing to mental irritability, fifty-four to drowsiness, sixty-three to lassitude, forty-two to giddiness, thirty-three to a sense of intoxication, nineteen to anorexia, thirteen to nausea, eleven to vomiting, and twenty-one to salivation. Many admitted that drowsiness and lassitude had become less troublesome after they had been employed for some time in this occupation, and several stated that they did not feel well until they had sprayed lacquer for some time in the morning. It was a common experience for all the above symptoms to disappear after the employees had been away from work only for ten to fourteen days. None of the masks provided by the workshops were in use, the objection to them being that, if made to fit properly, they were uncomfortable. It is stated that, in addition to forced ventilation in workshops, the elimination of the most toxic solvents of duco-lacquer would do much to reduce its poisonous effects.

312 Early Symptoms of Blood Diseases

C. HEGLER (*Med. Welt*, January 6th, 1934, p. 12) stresses the importance of a precise anamnesis for the early recognition of blood diseases. A hereditary disposition may thus be discovered and facilitate diagnosis at an early stage of such diseases as haemophilia, haemolytic icterus, polycythaemia, and pernicious anaemia. For the last-named disease he accepts a proportion of 6 to 8 per cent. hereditary cases as average. A further indication of possible blood affection is given by certain occupational data. Tropical diseases, syphilis, undernourishment, and previous x-ray treatment, if established in the anamnesis, are also valuable diagnostic factors. Subjective symptoms mostly appear only at comparatively late stages. Enumerating the latter, Hegler mentions that the condition of the skin gives an early warning in lymphogranulomatosis, chronic myeloid leukaemia, and Hodgkin's disease; the swelling of lymph nodes forms one of the earliest subjective and objective symptoms of chronic lymphoid leukaemia; violent nose-bleeding should, he states, always be regarded as an indication for measuring blood pressure and making a blood count, as it is an early symptom of many blood affections; glossitis often occurs early in pernicious anaemia and Biermer's disease, while bleeding of the gums points to polycythaemia and acute myeloid leukaemia. Loss of appetite, dyspepsia, and hiccups often appear as early signs of myeloid leukaemia, while vomiting and abdominal pains may be the precursors of polycythaemia. Accentuation, or premature cessation, of the sexual functions may usher in acute myeloid leukaemia or pernicious anaemia; impaired hearing and Ménière's symptom occur early in leukaemia, and violent bone pains in Hodgkin's disease. The author concludes that although no practitioner can be expected to be familiar with all details of modern

haematology and to interpret correctly every blood picture, it is really important for every practitioner to know when to suspect the presence or imminence of a blood disease, and when to consult the haematologist.

313 Tonsillectomy for Focal Infections

R. GORDING (*Tidsskr. f. d. Norske Lægefor.*, January 1st, 1934, p. 1) has taken a random sample of seventy-nine records of tonsillectomy performed in private practice a year or more earlier. The operation was performed in twenty-nine cases only for local symptoms, and in nine cases for polyarthritis. There remained forty-one cases (twenty-eight women and thirteen men) in which the operation was indicated on account of general symptoms interpreted as those of a focal infection. These general symptoms included lassitude, irritability, and various aches and pains. Some of the patients were apt to be febrile, but articular symptoms were subordinate, and were limited to a transient sense of stiffness. In most of these forty-one cases the symptoms had lasted a year or two. The average age was about 30 years. Results were as follows: In four cases little or no benefit was derived from the tonsillectomy; in the remaining thirty-seven cases it was followed by improvement, the symptoms in most of the cases diminishing after three or four weeks; in some cases the tonsillectomy was promptly followed by the cessation of pain; in eight of the forty-one cases blood counts were made and showed, in seven cases, the characteristic picture of a high leucocyte count with left displacement. Two types of tonsil were commonly observed—a small tonsil embedded in the surrounding tissues, partially or completely hidden by the anterior palatine arch, and a large boggy tonsil, its anterior and upper portion being particularly hypertrophied. Though he has achieved such a high proportion of successes, the author dwells on the difficulties of incriminating, before operation, the tonsils in connexion with various general symptoms, which may be due to a great number of other causes. Neither a clinical nor a bacteriological examination of the tonsils beforehand can be relied on; even when haemolytic streptococci are obtained in pure culture, their host may appear to be blissfully fit.

314 Dietary Adequacy in Diabetes Mellitus

J. A. NIXON (*Practitioner*, January, 1934, p. 25) deprecates the continuance of emphasis on carbohydrate restriction in diabetes mellitus: this often results in the diet being inadequate. He maintains that with the correct employment of insulin a full and satisfying dietary can often be adopted. Having decided on an adequate maintenance diet in terms of protein and calories, the latter must be apportioned between the protein, fat, and carbohydrates. Details are given of the way in which the necessary calculations can be made. As regards the carbohydrates, white bread is particularly valuable, since it contains almost constantly 50 per cent. of these, or 15 grams in each ounce. Nixon describes white bread as the most palatable and economical form of carbohydrate food, the wastage in the faeces being minimal. Certain puddings and sweets can also be allowed, potatoes need no longer be excluded, and the "satiety value" of the meal can thus be materially raised with beneficial results. Diabetic diets should be as nearly as possible identical with those appropriate to healthy persons of like age and occupation. On the whole, diabetics are better without alcohol; it is apt to upset calculations as to carbohydrate utilization and glycogen storage in various ways. The author adds that there is no merit in prescribing large quantities of green vegetables and fat, and that bread substitutes are unnecessary. All that is required is to measure the quantities of the food carefully in relation to the increased capacity rendered possible by insulin, permitting the same proportions of carbohydrate as are regarded as physiologically reasonable for the healthy.

Surgery

315 Operative Treatment of Undescended Testicle

T. WALHEIM (*Hygiea*, January 31st, 1934, p. 49) has investigated the post-operative histories of recruits treated in a military hospital in Stockholm for undescended testicle. In the period 1914-25 eighty-three such cases were observed, the average age being 20 to 21. In eight cases no operation was undertaken, and in eight other cases the patients could not be traced. In two cases the testicle could not be found, either in the inguinal canal or in the abdominal cavity, and in one case the testicle was removed because of torsion of the cord with necrosis of the testicle. Among the remaining sixty-four cases there were thirteen in which the testicles were found in positions not normally occupied either in foetal or in post-foetal life. In 45 per cent. of the operated cases there were also clinical signs of an inguinal hernia. After describing the technique of the operation employed (mobilization of the testicle in such a way that it remains in its new position in the scrotum without any fixation there) the author summarizes the findings of an inquiry by correspondence. Only fifteen of the ex-patients presented themselves for re-examination; the others answered the questionnaire sent them. The cases were classified according to the positions originally occupied by the testicles; there was no great difference in the results of the operation in these various positions. In as many as seventeen cases the testicle had become larger after the operation, attaining the size of its fellow in two cases. In only one case had the operation been followed by atrophy of the testicle. As four of the sixty-four cases were bilateral, there were altogether sixty-eight operations, fifty-four of which were performed by one and the same surgeon. In his material the results were excellent after thirty-eight operations, good after fourteen, and less good after two. The results of fourteen operations by other surgeons were excellent in nine cases, good in two, and less good in three. These results are much more encouraging than those published in 1912 by Hofstätter, who found in the twenty-seven different operations devised for undescended testicle intrinsic evidence of their faultiness.

316 Portal Thrombosis after Gall-stone Operations

According to F. ROST (*Zentralbl. f. Chir.*, January 20th, 1934, p. 159) thrombosis in the portal vein is a common cause of death, apparently due to heart failure, after gall-stone operations: it is often first diagnosed at necropsy. The two clinical signs which Rost has come to recognize as showing portal thrombosis are: (1) sudden and pronounced weakening of the pulse, in the absence of dyspnoea, cyanosis, and severe pain, with failure of response to stimulants or infusions; and (2) a psychic alteration, with dreaminess and retardation. The second sign, which is akin to the psychosis seen in large hepatic sarcomata, is probably due to destruction of the liver parenchyma. The commonly described signs of portal thrombosis—swollen belly, blood in the vomit and motions, splenic enlargement and ascites, with acute pain simulating pancreatitis or ruptured viscus in acute cases, and in the more chronic ones terminal bowel gangrene and peritonitis—have not been met in Rost's experience.

317

Coxa Vara

H. CAMITZ (*Acta Chir. Scand.*, January 15th, 1934, p. 521) doubts if the mechanism of the various forms of coxa vara will ever be completely elucidated only by histological investigations, but, having recently conducted such investigations in three alleged cases of congenital coxa vara, his scepticism has grown as to the very existence of such a condition. It was defined in 1905 by Hoffa on the basis of radiographic, clinical, and histological examinations of two children, aged 3 and 4 years respectively. He concluded that the bony system must have undergone some morbid changes during intrauterine life which led to the outbreak of what he called congenital

coxa vara some years later. In support of this hypothesis it has been pointed out that this disease has sometimes been found in more than one member of the same family or has occurred bilaterally. It has, however, been noted that this disease has never been found at birth nor before the child has begun to walk. In two of the author's cases, aged respectively 14 and 13 years, a partial resection of the neck of the bone provided him with material for a histological examination. The third case was that of a 6-year-old boy who was admitted to hospital for congenital coxa vara, and who died of pneumonia before any operation could be attempted. The author has come to the conclusion that there is no reliable evidence to support the view that coxa vara can be of congenital origin, and for cases which have hitherto been labelled congenital he would like to substitute the term "infantile coxa vara." His researches suggest that ordinary coxa vara, infantile coxa vara, and osteochondritis deformans juvenilis (coxa plana) are but three variations of one and the same developmental ailment, which occurs while the child is growing and is due to defective ossification.

Therapeutics

318 Vaccinal Serum in Post-vaccinal Encephalitis

E. SARDEMANN (*Ugeskrift for Laeger*, January 4th, 1934, p. 10) reviews the results hitherto achieved by the administration of the serum of a recently vaccinated person to cases of encephalitis following vaccination. The literature includes fifteen such cases, only two of which ended fatally. The author adds to this material a new case—that of a girl, aged 6 years, admitted to hospital with the diagnosis of acute anterior poliomyelitis. She had been vaccinated fourteen days earlier. Though the cerebro-spinal fluid showed various morbid changes, no tubercle bacilli could be found in it by staining, culture, or guinea-pig inoculation. Post-vaccinal meningitis having been diagnosed, 10 c.cm. of serum taken from a recently vaccinated adult were given by intramuscular injection, and a similar dose was given next day. Recovery was protracted and not complete on the patient's discharge. From his study of the literature the author comes to the conclusion that the persons most subject to post-vaccinal encephalitis are children about the age of 5 or 6. The Dutch statistics covering the three-year period 1924-6 show that 79 per cent. (ninety-eight out of 123 cases) occurred between the ages of 3 and 5. It has therefore been suggested that children should be vaccinated as early as possible, long before this dangerous age is reached.

319

Treatment of Bilharziasis

F. G. CAWSTON (*Journ. Trop. Med. and Hyg.*, January 15th, 1934, p. 22) indicates lines on which the value of treatment of this disease can be assessed; he urges the importance of recording clinical results to this end. There is, he states, need of a shorter and more effective course of treatment than that of tartar emetic, and "neostam" might prove to be a more suitable drug. Cawston points out that a juvenile with a heavy infection tolerates and requires a larger dose of tartar emetic than does a slightly infected adult; dosage should therefore be calculated on the number of parasites to be destroyed rather than on the age and weight. Early infections are not more easy to cure than old-standing ones. Colloidal preparations of antimony are of limited value in the treatment of schistosomiasis, but the addition of sulphur to overcome the toxic effects of this metal is commended. The mere absence of ova in the urine is not conclusive evidence of the cure of the disease. The author believes that the complete destruction of the parasites can best be effected by two courses of treatment with "fouadin," separated by an interval of a few weeks. This is better than a more intensive course with the risk of toxic effects from excessive doses or daily injections. The death of the schistosomes depends more on the gradual changes in the constitution of the blood while the patient is under

treatment—as shown by blood tests and the acquired tolerance to the drug which develops provided that the necessary doses are not exceeded—than on the direct action of the antimony. Rapid cures are not desirable. Toxic effects from antimony therapy may be avoided by using skilfully regulated doses of the potassium salt in fresh solution.

320 Massive Dosage of Liver Extract in Pernicious Anaemia

J. LENDVAI (*Orvosi Hetilap*, 1934, i, 2) has used single doses of 20 c.cm. "campolon" liver extract intramuscularly (instead of the usual daily injections of 2 c.cm.) with satisfactory results. Such a large dose of liver extract led to a crisis in the reticulo-endothelial system, followed by definite improvement in the blood picture and the patient's general condition. In cases which had not had previous liver treatment one of these 20 c.cm. doses sufficed; otherwise two doses were necessary to effect complete recovery. Where the disease was complicated by paraplegia, paraesthesia, anaesthesia, etc., three or four doses were required. The treatment carried out on twenty-five patients is claimed to have been successful in every case. The remission obtained lasted for from three to twelve months, but in cases with complications it was shorter. The author advises that this treatment should be carried out every two or three months in order to prevent relapses.

321 Sodium Dihydrophosphate in Diabetes

A. LACROZE (*Semana Médica*, January 25th, 1934, p. 291) urges that the neuro-muscular, neuro-circulatory, and neuro-psychical forms of depression so frequent in the diabetic—especially the first and third—yield rapidly and completely to treatment with this salt, of which he gives 2 grams once or twice daily after the chief meals. He has noted an immediate improvement in capacity for muscular exertion, and a sensation of euphoria and calm from eight to ten days after the initiation of the treatment. The capacity to concentrate, to remember, and to engage in prolonged conversation were all substantially increased. Some authors have spoken of the congestive action of phosphoric acid on the liver, but Lacroze saw no sign of this. He mentions two interesting facts—first, that administration of this salt neither provoked nor increased the elimination of ketones by the urine, and secondly, that neither pyrosis nor any symptom of hyperchlorhydria was present.

Neurology and Psychology

322 Acute Neuromyelitis

Many cases of this apparently new neurotropic infection—a neuromyelitis or a myelitis clinically resembling the ascending paralysis of Landry—have been noted during recent years. A. AUSTREGESILLO (*Rev. Sud-Amér. de Méd. et de Chir.*, October, 1933, p. 713), reviewing the affections collectively attacking the nervous system (encephalitis lethargica, etc.), believes that a neurophilic virus is the causal agent of diverse diseases, particularly during the course of influenza. Notes are given of ten cases, presenting both neuromyelitic forms (of polyneuritic onset with myelitic complication or termination) and bulbar forms. The prognosis of this malady is always grave. The onset may be severe or slight; frequently only malaise, lassitude, pains, or anorexia are noted. Polyneuritic symptoms (numbness, pains, weakness, usually in the lower, more rarely in all the limbs) appear in from a few days to four months. These may attenuate or totally disappear; they are of a motor type with changes of the subjective sensibility. Later, medullary or bulbar manifestations, resembling acute myelitis, supervene. Sphincteric troubles are constantly present. Dysphonia, dysphagia, and dyspnoea and tachycardiac crises are the most frequent bulbar symptoms. Muscular atrophies and myalgias are common.

Usually the deep reflexes are abolished; the superficial reflexes may also be absent or only present in slight degree. Babinski's sign may be noted, especially in chronic cases, and vasomotor symptoms may also occur. Only during the course of the disease when medullary symptoms persist is a certain degree of spasm noted. The results from lumbar puncture are not uniform. Often the infectious phase, which may assume an influenzal, typhoid, or slight general infectious form, precedes the neurological syndrome. In some cases recurrences aggravate the condition, which either becomes chronic or ends fatally. Two cases are cited of the fulminating type, bulbar symptoms occurring early with a rapidly fatal termination.

323 The Barbiturates in Neuropsychiatry

C. P. WAGNER (*Journ. Amer. Med. Assoc.*, December 2nd, 1933, p. 1787) points out that, while the barbituric acid derivatives are usually employed for their sedative action, their various side actions have some therapeutic value in neurosis. Thus, the longer-acting drugs may be used successfully in the treatment of a psychosis with cerebral arteriosclerosis. Given in small doses three or four times a day with potassium iodide they decrease agitation and motor restlessness and reduce the hypertension. The shorter-acting drugs must be used with extreme caution in such cases because the fall in blood pressure which usually accompanies their administration results in a feeling of dizziness, and may lead to collapse. It must be remembered also that the longer-acting drugs are excreted more slowly, and the cumulative effect of them when administered for a long time may lead to delirium. When difficulty occurs in falling asleep, one of the shorter-acting barbiturates, such as sodium amytal, is often effective, but if the sleep is broken by periods of wakefulness during the night a longer-acting drug is advisable. Too early waking may be treated by a short-acting drug, sodium amytal or pentobarbital sodium (nembutal) being given on waking. The drug is eliminated in a few hours, and the patient, having gone to sleep again quickly, eventually wakes free from depression. Deep narcosis for several days is sometimes advisable, and the barbiturates of the longer-acting kind are appropriate in these cases, since they promote physiological and psychological rest. Better co-operation in treatment often follows the administration of small doses of sodium amytal, which can be continued for three or four weeks. This may interrupt the neurosis and hasten recovery. Wagner adds that toxic symptoms most commonly arise from the too long exhibition of moderate doses.

324 Recurrent Narcolepsy following Lethargic Encephalitis

S. KOSTER (*Nederl. Tijdschr. v. Geneesk.*, February 24th, 1934, p. 883) records the case of a young man, aged 19, who suffered from recurrent hypersomnia following lethargic encephalitis. The attacks occurred at first every month, and afterwards the intervals varied in length from three to fourteen months. The encephalitis had occurred five years previously. The case was of special interest owing to the long duration of the hypersomnia, which always lasted for a week, the absence of any other symptom of an organic lesion except a facial tic, and the fact that large quantities of food were consumed during the periods of hypersomnia.

325 Neurinoma of the Cervical Sympathetic

According to M. AMANO (*Zentralbl. f. Chir.*, January 13th, 1934, p. 78) the cervical sympathetic, although frequently affected in von Recklinghausen's generalized neurofibromatosis, is rarely (as in two cases now described) the sole site of a neurinoma. The patients were males, aged about 40; the tumours had existed six and ten years respectively; one of them had ptosis and myosis, which persisted after excision of the tumour. This was a neurinoma—of fibrillary type in one case, in the other partly fibrillary, partly reticular, with blood-cystic degeneration which predominated in the clinical signs.

Obstetrics and Gynaecology

Pathology

326

External Version

L. M. RANDALL (*Proc. Staff Meetings Mayo Clinic*, January 3rd, 1934, p. 5) urges the more frequent practice of the Wiegand or external version procedure in cases of transverse or breech presentations in primiparae, and especially when the latter condition is associated with pelvic contraction. The best time for it is stated to be the thirty-sixth week of pregnancy, but it is better to perform the manipulation too early, and to have to repeat it, than to wait too long. The pressure should be gently applied, and no attempt should be made to turn the infant if the breech cannot be dislodged from the lower segment of the uterus or the inlet of the pelvis. No manipulation should be made during a contraction of the uterus. If the organ is very irritable, it is better to give a sedative by mouth or hypodermically, or even to anaesthetize the patient, than to persist in manipulation in the presence of a tonic uterus. As a rule, version is started by elevating the breech and pushing it towards the side of the uterus which is occupied by the foetal back. Frequent observation of the position and presentation of the foetus in the last two months of pregnancy is desirable in order that unfavourable presentations may be corrected if possible. A radiogram is sometimes advisable, particularly when version cannot be performed or when there is a spontaneous return to a breech position after external version, since some anomaly of the infant may thus be detected. When the change in presentation has been achieved the patient is allowed to be up, but is examined after a week. The author does not advocate the use of binders. He has not encountered such complications as placental detachment, twisting of the cord, and premature labour.

327

Pregnancy and Heart Disease

CARR and HAMILTON (*Amer. Journ. Obstet. and Gynecol.*, December, 1933, p. 824) report observations on a continuous series of 500 definite cardiac cases during twelve years: 94 per cent. were rheumatic and 77 per cent. of these had mitral stenosis. Hypertension was only slightly commoner than in patients with sound hearts. Auricular fibrillation, probably owing to the low age limit for pregnancy, was of small incidence—fourteen cases only—but of high fatality (43 per cent.). This is noted as remarkable when compared with the number (thirty-four) treated for toxæmia. Paroxysmal tachycardia is not dangerous, except when serious heart damage is also present. Post partum only four cases had symptoms attributable to their heart disease originating after confinement, so that the problems occur before cardiac patients come to delivery. Of the fatal cases twenty-seven were of rheumatic origin and twenty were congestive; two had congenital morbus cordis, two hypertensive hearts, and one bacterial endocarditis. With reference to the last, the prognosis for the mother is hopeless, but she may have a living child, so that therapeutic abortion is not called for. In congenital morbus cordis—2.4 per cent. of the 500—prognosis proved best when there was no communication between right and left sides of the heart. The maternal death rate was reduced from about 12 per cent. to nearly 3 per cent. Foetal mortality was 18 per cent., 500 cardiac mothers producing 416 viable babies. The authors' deductions are as follows. The clearly bad risks are: (1) cases of present or precedent congestive heart failure; (2) damaged hearts in the presence of other complications. Active or recent rheumatism is a temporary contradiction of pregnancy. Age above 35 doubles the risk. Cardiac patients must be rigidly controlled by a regime prescribed individually. There must be no over-exertion or fatigue, they must be confined to bed at the slightest sign of a cold, and even trifling symptoms must be reported. The earliest reliable clinical sign of failure is rales at the lung bases. Rapid delivery must be secured. Ether or $N_2O + O_2$ without previous medication is preferred.

740 D

328 The Immunology of Staphylococcus Toxin

W. A. JAMIESON and H. M. POWELL (*Amer. Journ. Hyg.*, January, 1934, p. 246) have studied the production of staphylococcal toxin and antitoxin, and their value in the treatment of pyogenic infections in man. They find that only a few strains produce a potent toxin, and that the best medium for its formation is a semi-solid agar. The best toxin was necrotic to the rabbit's skin in a dose of 0.001 c.cm. Rabbits were immunized with increasing doses, and sera were obtained that neutralized up to 5,000 skin necrotizing doses per c.cm. Higher values still, up to 20,000, were observed in the sera of experimentally immunized horses. Staphylococcal toxin, diluted from 10 to 50 per cent. with saline and preserved with 1 in 10,000 merthiolate, was used in place of the usual vaccines for the treatment of patients with furunculosis, acne, prostatitis, and phlebitis. No evil effects were noticed, and in some cases the response appeared to be favourable. Attempts at the passive immunization with horse antiserum of patients suffering from severe staphylococcal infections had little or no success, though the results appeared slightly more promising when the predominant feature of the case was intoxication.

329 Amyl Nitrite and Sodium Hyposulphite in Potassium Cyanide Poisoning

Experimenting on rabbits, A. BUZZO and R. E. CARRATALÁ (*Semana Médica*, December 7th, 1933, p. 1772) record success in 80 per cent. of all cases treated with inhalations of amyl nitrite associated with intravenous injections of sodium hyposulphite, even after the animals had taken very many times more than a lethal dose of potassium cyanide. They declare that the hyposulphite is almost non-toxic to the rabbit and is manifestly superior to sodium nitrite, which is poisonous, even though when given in fractional doses it has been sometimes successfully employed in cyanide poisoning. Rabbits subjected to inhalation of amyl nitrite did not succumb until it had been kept up for fifteen minutes continuously. The experiments performed were as follows. With a stomach tube the cyanide was introduced into the stomach of the rabbit, after which 4 or 5 grams of hyposulphite were injected into a vein. Simultaneously inhalations of Martindale's amyl nitrite were given for fifteen to forty seconds, every three or five minutes at the commencement, but with lengthened intervals if the pulse and respirations approximated the normal rates, so that finally the drug was being administered only every two or, in some cases, every five hours. Success was achieved in all cases in which the poison had been administered in fourteen times the lethal dose, and in eight cases out of ten in which the animals had received doses sixteen times greater than this.

330

Experimental Rickets

M. DE BRUIN (*Nederl. Tijdschr. v. Geneesk.*, January 27th, 1934, p. 397) found that rats fed on a diet consisting mainly of oatmeal contracted rickets in a much more marked degree than rats fed on rice. In both diets the absolute values of calcium and phosphorus were the same, the proportion of calcium to phosphorus being 4 to 1. No difference was observed between the intensity of rickets on a diet in which the rice or the oatmeal had previously been extracted by ether and the untreated cereals. Addition of ethereal rice extract or oatmeal extract to the original diets did not perceptibly affect the intensity of rickets. On addition of barley extract, however, to the oatmeal diet the development of rickets was markedly inhibited, as had already been shown by De Ruyter, De Wildt, and Brouwer. It is added that barley probably contains a considerable amount of vitamin D.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

331 Tuberculosis in Asylums

A. J. NISSEN (*Tidsskr. f. d. Norske Lægefor.*, January 15th, 1934, p. 78) has investigated the incidence of fatal tuberculosis in the asylum in which he works, and also in all the Norwegian asylums between 1872 and 1929. Of the approximately 6,600 mental patients residing in asylums in any year at the present time, some 110 die of tuberculosis annually. About 30 per cent. of all the asylum deaths are due to tuberculosis, and about 2.6 per cent. of all the deaths from tuberculosis in Norway occur in asylums. Considering that only 2.4 per 1,000 of the population are accommodated in asylums, this ratio is most impressive, and the author calculates that the tuberculosis death rate is approximately ten times greater inside than outside asylums. In the period under review there were 57,677 admissions to asylums (several patients were readmitted once or oftener). In the same period there were 2,758 deaths from tuberculosis within the asylums. A chart showing the incidence of these deaths in twelve different periods indicated little change from one period to another, but the curve showed a tendency to rise steadily, reaching its maximum height in the period 1917-21. It should be noted in this connexion that during the period under review the average number of days spent by each patient in an asylum has risen from 593 to 1,209. The average age of the patients has also risen, and there has been an increase in the proportion of cases of dementia præcox in relation to the other diseases. This is a disease with a tuberculosis mortality of about 50 per cent. The high tuberculosis mortality in asylums does not concern them alone, for every year some 1,300 to 1,400 patients are discharged and may become sources of infection to their neighbours. The author recommends systematic Pirquet examinations of all new patients on admission, the test to be repeated later if negative.

332 Subacute Poisoning from Luminal and Bromine Derivatives

J. ZAPPERT (*H'en. med. H'och.*, No. 1, 1934, p. 14) draws attention to the risk, illustrated by three cases, of diagnosing tumour of the brain or some other lesion when all the signs and symptoms are due to subacute poisoning with luminal and bromine derivatives given over a considerable period, but left out of account when a practitioner presents the case to a consultant. In one of these cases, a boy of 5, the consultant was presented with the diagnosis of tumour of the brain from the outset. The practitioner stated that the symptoms had begun with attacks which he had interpreted as epileptic. Subsequently, headache, vomiting, lassitude, and definite ataxia had set in. Meanwhile the epileptic fits had ceased. The child looked very ill and had a staggering gait. His speech was slow and monotonous. In addition to a high degree of drowsiness there was slight ptosis, with tremor of the tongue and arms. Even with his eyes open the child presented a high degree of ataxia, but his intelligence appeared to be normal and there was no disturbance of vision. Later, it transpired that the child had been given 0.1 gram of luminal daily for several months, and that, in order to supplement its supposedly inadequate effects, a bromine derivative had also been given daily for some weeks. The child recovered promptly when these sedatives were discontinued, and the recurrence of the epileptic fits was met by moderate doses of luminal. Though these cases are cited as a warning against the prolonged exhibition of sedatives, the author does not accept the common view that the prolonged action of bromine derivatives weakens the patient's intelligence. This view is, he states, probably due to a misinterpretation of the observation that though bromine often reduces the number of epileptic fits, it does not diminish the characteristic mental features of the epileptic.

333 Nephritis following Infectious Diseases

V. BIE (*Ugeskrift for Læger*, January 4th, 1934, p. 1), who is in charge of a Danish fever hospital, has come to the conclusion that the overwhelming majority of cases of acute haemorrhagic nephritis are due to acute infectious diseases. Scarletina is the disease most frequently complicated by nephritis. Among 1,200 cases of scarlatina treated in hospital in 1915, there were sixty complicated by nephritis, the date of onset of which was noted in all but two cases. Though the textbooks are inclined to teach that the onset of such nephritis occurs nearly always during the third or fourth week of the scarlatina, the author found that among his fifty-eight cases there were only thirty-one in which the nephritis appeared during this interval. Nine cases developed before it and eighteen after it. The extreme limits were the first and sixty-fourth days of the scarlatina. Apart from these cases of acute nephritis developing in connexion with epidemic diseases such as scarlatina, there were fifty-four cases treated in hospital between 1929 and 1932 in which the aetiology was as follows: unknown, fifteen cases; angina faucium, sixteen; erysipelas, nine; pneumonia, eight; septicaemia, four; rheumatic fever, one; and pulmonary tuberculosis, one. During the same period the number of cases of angina faucium treated was 2,600. The corresponding numbers for erysipelas and pneumonia were 550 and 1,100 respectively. These figures show that haemorrhagic nephritis is a comparatively rare sequel to the above-mentioned diseases. While most textbooks put the onset of haemorrhagic nephritis at the third or fourth week after the development of an angina faucium, the author has found that both in angina and in erysipelas this complication appears at the outset of the primary disease, at the latest within a week of its onset.

Surgery

334 Primary Carcinoma of Ureter

W. W. SCOTT (*Surg., Gynecol. and Obstet.*, February, 1934, p. 215), who records two illustrative cases in men aged 55 and 36 respectively, states that primary carcinoma of the ureter is a relatively rare disease, there being only sixty-one acceptable cases in the literature. The most common type of tumour is papillary carcinoma. The disease occurs with equal frequency in the fifth, sixth, and seventh decades of life. The right ureter seems to be attacked slightly more frequently than the left, the lower third being involved in 5.7 per cent. of the cases. The post-operative mortality in forty-four cases was 27 per cent., but of the cases which were followed up only two were reported within five years after operation.

335 Kienböck's Disease of the Semilunar Bone

A. RINGSTED (*Hospitaltidende*, January 16th, 1934, p. 57) discusses the treatment of Kienböck's disease of the wrist in the light of fourteen cases on which he has operated. When this disease was first defined in 1910 by Kienböck, he regarded it as a post-traumatic osteomalacia of the semilunar bone. Many surgeons, however, consider this condition as nothing more than a compression fracture, and it must be admitted that, a day or two after an accident, such fractures have been found at an operation, or on post-mortem or x-ray examination. On the other hand, in more than half of the cases on record there was no history of trauma, and even in the so-called traumatic cases the injury was rather a strain than anything more violent. In six of the author's cases there was a moderate degree of trauma just before the first appearance of symptoms. In 139 of the 231 cases collected from the literature by Christensen there was a history of trauma, for the most part slight. The author concludes that the

aetiology is still obscure, that none of the hypotheses hitherto advanced in explanation of the genesis of this condition is correct, but that it is quite clear that necrosis of the bone is demonstrable in all recent cases. The treatment most suitable is also still in dispute; but the author's survey of the literature suggests that, on the whole, better results can be achieved by operative than by conservative treatment. His fourteen cases were represented by thirteen patients, in one of whom the semilunar bone was removed on both sides. In all the cases the semilunar bone was removed through a dorsal incision, and the space thus created was filled by a fat graft, taken from the thigh, and encouraged to attach itself to the surrounding structures by the scraping away of the cartilages of the neighbouring bones. In eight cases a cure, and in three improvement, was effected. In the remaining three cases there was no change.

336 Results of Gastrectomy for Gastric and Duodenal Ulcer

In the opinion of W. RIEDER (*Zentralbl. f. Chir.*, January 27th, 1934, p. 198) the results of gastric resection for peptic ulcer, in properly chosen cases, are so good that to return to gastro-enterostomy would be unjustifiable. He publishes records of 574 gastrectomies for peptic (including a few post-operative jejunal) ulcers, with 5.9 per cent. mortality; perforation cases are not included. Of the 254 cases which could be traced, about 75 per cent. were cured (free from pain and the necessity of dieting); if fifteen secondary operations and twenty-five resections done in the absence of ulcer be deducted, cures amounted to 80 per cent. The same percentage of success was attained in sixty-three traceable cases of resection for perforated ulcer. The non-cured cases, which included three recurrences of ulceration, were all associated with absence of free hydrochloric acid; they appeared to be due chiefly to gastritis, but some to adhesions, duodenitis, or jejunitis. Except in neuropathic subjects the unsuccessful cases responded to prolonged treatment by pepsin and hydrochloric acid. E. KOCH and BELOZER-KOVSKY (*ibid.*, March 3rd, 1934, p. 486) report 94 to 96 per cent. of lasting cures after primary stomach resection for peptic ulcer. They quote the reported proportion of 0.8 per cent. of jejunal ulcers occurring subsequently, as contrasted with 1.5 to 10 per cent. after gastro-enterostomy. They cite three cases from the literature, and three from 427 gastric resections for ulcer in Sokolow's clinic, of gastrocolic fistula resulting from penetration of a jejunal ulcer, and point out the importance of early treatment of jejunal ulcer, lest a gastrocolic fistula—which is inevitably fatal in spite of temporary improvements after medical treatment, and which calls for an extensive and serious operation—should result. The operative mortality in the 427 cases was 6.3 per cent.

337 Solitary Cysts of the Kidney

B. GREENBERG, M. BRODNY, and S. ROBINS (*Amer. Journ. Surg.*, February, 1934, p. 271) report ten cases of solitary cyst of the kidney. These cysts are usually voluminous and non-parasitic, single and generally unilateral, containing serous fluid, and growing in a comparatively normal kidney. They originate in the renal cortex, are slow in development, and are benign. In the cases described the average age was 56, and although in this series the sexes were equally represented, the lesion is usually twice as frequent in women. The right kidney is the most common site, particularly in the lower pole, although the cases reviewed did not agree with general statistics. The symptoms of renal cysts are vague owing to the slow growth of the disease, and vary according to the site and size of the cyst. Large cysts of the upper pole cause diaphragmatic pressure and irritation with resulting dyspnoea, cough, and pain in the chest and shoulders. Cysts of the lower pole exert pressure on the intestines and stomach and may cause gastro-intestinal symptoms such as epigastric pain, vomiting, and loss of appetite. These cysts, unlike those of the upper pole, can usually be palpated. Diagnosis by pyelography or

x rays alone is difficult, but intravenous urography intensifies the outline of the cyst and demonstrates changes in the size and shape of the kidney. In about 40 per cent. of cases of solitary cysts additional pathological lesions are present, and in the ten cases reported there were two with tumour of the kidney, two with renal calculi, and one with associated cyst of the liver. The best results are obtained by complete excision of the cyst.

Therapeutics

338 Subcutaneous Oxygen in Pulmonary Embolism

J. L. H. SPECKEN (*Nederl. Tijdschr. v. Geneesk.*, January 20th, 1934, p. 274), who records an illustrative case, emphasizes the value of subcutaneous injection of oxygen in pulmonary embolism. The technique is simple and almost painless: 400 c.cm. can easily be injected into the subcutaneous tissue of the abdominal wall. Specken's patient was a woman, aged 39, who, four days after supravaginal amputation of the uterus for chronic endometritis, developed symptoms of embolism. No benefit was derived from the administration of stimulants and pantopon, but rapid recovery followed subcutaneous injection on three consecutive days of 400 c.cm. of oxygen.

339 Vaccine Treatment of Hay Fever

E. WESSELY and V. KOERBEL (*Wien. med. Woch.*, January 27th, 1934, p. 124) began by treating their cases of hay fever with injections of pollen extracts chosen in each case to correspond to individual idiosyncrasies. The successes achieved were at the cost of considerable trouble. Accordingly, during the past year they have made use of a standard extract containing a mixture of substances. Twenty cases of hay fever were given subcutaneous injections of steadily increasing quantities of this extract, at first three times a week, and later twice a week. Focal reactions were frequent in the form of snuffling, sneezing, and (less frequently) nasal obstruction and conjunctivitis. When the higher doses were reached, and frequently also quite early in the treatment, there would be a transitory general reaction consisting of universal itching, urticaria, congestion, lassitude, palpitation of the heart, asthma, fever, shivering, and diarrhoea. There was often a severe reaction to small doses in patients who later tolerated much higher doses with impunity or only little discomfort. The most severe of the general reactions, observed in five cases, passed rapidly off in response to rest, black coffee, and the application of an ice-bag to the heart. Most of the patients were tired for several hours after an injection. In two cases an old articular rheumatism, and in one case psoriasis, flared up again. In compensation for all these discomforts, freedom from hay fever was achieved by eight patients, considerable improvement by ten, and a moderate degree of improvement by two. In other words, the effects of this treatment, as far as the hay fever was concerned, were invariably more or less beneficial.

340 Intravenous Injections of Alcohol in Pulmonary Abscesses

V. HINKOVA (*Thèse de Paris*, 1934, No. 18), who records twelve illustrative cases in patients aged from 5 to 55, maintains that intravenous injection of alcohol is often effective in the treatment of pulmonary abscess. Although, according to Professor Sergeant, pulmonary abscess requires surgical treatment at the end of six weeks, medical treatment by alcohol should first be tried, although the mechanism of its action is still obscure. The technique is as follows: 20 c.cm. of absolute alcohol is mixed with 80 c.cm. of isotonic glucose solution, or 33 c.cm. of absolute alcohol with 67 c.cm. of isotonic glucose solution. The injections are given daily or every other day, six to twelve injections being usually required. As a rule rapid improvement results, and there is no need to continue the treatment if a distinct clinical or radiological improvement does not take place after ten injections.

Anaesthetics

341. Pernocton plus Posterior Pituitary Extract as a Labour Anaesthetic

According to H. BRAMMER (*Schmerz Narkose-Anaesthetie*, November, 1933, p. 59) "twilight sleep" is now secured at the Freiburg Universitäts-Frauenklinik by a combination of pernocton medication (partly intravenous, partly intramuscular) with injection of a posterior pituitary preparation from which the principles affecting blood pressure and intestinal peristalsis are absent. The combination eliminates the weakening of the pains which temporarily follows exhibition of pernocton; it is found to show an antispasmodic action on the rigid os. The initial injections are 3 to 4 c.cm. pernocton intravenously, 1 to 2 c.cm. intramuscularly, and 0.5 c.cm. of the pituitary extract intramuscularly. Not more than three hours "sleep" is secured, and additional injections of 1 to 2 c.cm. of pernocton intravenously as well as intramuscularly, with 0.5 c.cm. of pituitary extract, may then be required. By the combined treatment, in both primiparae and multiparae, it is possible to start the injections at an earlier stage (usually with the os at two to four fingers in primiparae). In spite of the earlier commencement the average duration of labour after the injections was about three hours in primiparae and two in multiparae. Amnesia was complete in ninety-nine out of 110 cases, and no foetal mortality was recorded.

342. Anatomy of Sacral Anaesthesia

According to L. ELAUT and G. VERDONK (*Zentralbl. f. Chir.*, January 6th, 1934, p. 12) current accounts of the surface anatomy of the posterior sacral foramina are erroneous in several important respects. Thus, the uppermost is not 4 cm., but only 2.7 cm., from the middle line, and the line joining the four foramina of one side is much less inclined upwards and outwards than is commonly stated. A line joining (1) a point 2.7 cm. external to the middle of the tangent to the iliac crests, and (2) a point 0.7 cm. external to the cornu of the sacrum passes through the four foramina in the great majority of cases. The fourth foramen is 1 cm. above the lower end of the line; the distances separating the fourth and third, third and second, and second and first are respectively 1.9, 2.2, and 2.5 cm. From the "regional" posterior superior spine—that is, the lowermost palpable point of the iliac crest—the second foramen is distant not 1 cm. but 2.5 cm. or even more. The four posterior foramina from below upwards are 1.75, 1.95, 2.1, and 2.3 cm. respectively from the middle line. The average height of the hiatus sacralis is 0.5 to 0.6 cm., and its breadth at the level of the cornu 2 cm. In eight of ten cases the hiatus does not extend above the third foramen. The injections should be done with the patient lying on the belly, the pelvis supported by a pillow. The needle should not penetrate more than 5 to 6 cm.; the dural sac is 8 cm. from the sacral cornu.

343. Evipan in Dental Anaesthesia

D. H. LE GOOD (*Pub. Dent. Service Gaz.*, January, 1934, p. 99) reports favourably on the use of evipan in this field, good results having been recorded in all except one of a consecutive series of fifty-three cases. In the unsuccessful instance there was restlessness with limb tremors, and coughing became exaggerated. Ether was required. Exposure of the drug in the syringe to light for five minutes before use was found to diminish markedly the muscular tremors. The drug was usually injected intravenously, but in five consecutive cases it was given subcutaneously, and in another five intramuscularly, in both series without any adverse local effects being noted. The muscular relaxation obtained was never sufficient to permit satisfactory orthopaedic manipulations. In most of the cases anaesthesia was required to last eight to twenty minutes; no case lasted longer than twenty-six minutes. Most patients received 10 c.cm., and

a maximum of 16 c.cm. has been given. Nearly all of the patients would otherwise have required endotracheal anaesthesia. With the one exception the anaesthesia was excellent; the cough reflex was always retained, and the bleeding from the gums was similar to that in ether anaesthesia. The patients usually awoke within thirty minutes after returning from the theatre, and after about fifteen minutes went to sleep again for three to five hours. The purely dental patients were all able to walk home nine hours after the extraction. Headache ensued in four cases some hours later, but was easily controlled by a mixture of phenacetin, aspirin, and caffeine.

344. Contraindications to Avertin Narcosis

A. A. FINOCHIETTI (*Semana Médica*, December 21st, 1933, p. 1999) gives a review of 300 personal cases in which this anaesthetic was employed. He states that it should not be used while local anaesthesia is practicable and will suffice. Amongst the contraindications he mentions shock and hypotension, blood diseases, conditions of dehydration, and acidosis untreated by glucose and insulin. As a general rule avertin should not, in his opinion, be used for gall-bladder surgery. In renal surgery damage to the parenchyma is a contraindication, while in respiratory conditions avertin should not be used where the lung function is much reduced. The author is also against its use in paralytic ileus and infections of the large intestine, rectum, and anus. In obstetrics non-cephalic presentations and a second stage with few and feeble pains are contraindications. The author states that during the anaesthesia CO₂ and ephedrine should always be handy.

Obstetrics and Gynaecology

345. Vesico-Vaginal Fistula

G. G. WARD (*Surg., Gynecol. and Obstet.*, January, 1934, p. 67) reports a case of vesico-vaginal fistula, with extensive loss of tissue, cured by the following plastic operation and a pessary. The author raised a flap of mucous membrane from the anterior wall of the vagina up to the fistula, and converted this, by sutures, into a tube. After preparing a bed for it, he drew the end of this tube through the original meatus, securing it there by means of sutures. This, the patient's eighth plastic operation, did not result in good control in the erect posture, but a completely satisfactory condition was arrived at by the insertion of a Thomas Hodge pessary in the reverse position. The pessary was warmed, and so moulded that the thick end gave just sufficient pressure on the urethra to prevent incontinence. The patient was able to remove, cleanse, and replace the pessary at will.

346. Aetiology and Treatment of Anaemia in Pregnancy

M. B. STRAUSS (*Journ. Amer. Med. Assoc.*, January 27th, 1934, p. 281) discusses the common anaemia in pregnancy, which appears to be of physiological aetiology. In many cases the condition would be more correctly described as a hydraemia, and consequent on change in the blood volume rather than on alteration of the corpuscular elements. Hypochromic anaemia in pregnant women is due, he thinks, either to a direct dietary deficiency or to a deficiency conditioned by gastric anacidity, hypo-acidity, or associated defects brought about by the foetal demand for blood-building materials. It may be completely relieved during or after pregnancy by the administration of iron, usually in large doses. According to Strauss the macrocytic anaemia is generally attributable to a temporary lack in the gastric juice of a specific intrinsic factor, which has been shown to be absent from the gastric secretion of patients with pernicious anaemia in the course of a relapse. This factor presumably returns after parturition. In other cases lack of an extrinsic factor (associated with vitamin B) in the diet may produce similar effects. This macrocytic anaemia may be entirely

relieved by the exhibition of liver extract, although iron is frequently required in addition. The author calls attention to the similarity of the aetiological mechanisms involved in the hypochromic anaemia of pregnancy and the idiopathic hypochromic anaemia which may occur in the absence of pregnancy; he also compares the macrocytic anaemia of pregnancy with pernicious anaemia. As bearing on the aetiological issue he remarks that disturbances of the gastric secretion occur to a greater or less extent in more than 50 per cent. of pregnant women. He concludes that the development of anaemia in pregnancy may best be prevented by ensuring that the diet is adequate as regards iron and protein. As a further precaution iron may be prescribed.

347

Uterine Inversion

Five instructive cases of inversion of the uterus are reported by D. BARROWS (*Amer. Journ. Obstet. and Gynecol.*, January, 1934, p. 105). All were recent and, except possibly in one case, occurred spontaneously. On admission to hospital treatment was by potassium permanganate douches, mercurochrome instillations, and vaginal packing, the elevated foot position being maintained. Case No. 1 was found to have recovered spontaneously and unexpectedly after three weeks of this treatment. Case No. 2 had had a placenta attached as though fibrous; relief was obtained by incision of the cervix per vaginam (Spinnelli operation), but two years later, after an apparently normal labour, the patient died owing to rupture of the scar. Case No. 3 also had a Spinnelli operation and was in good health four and a half years later, but had risked no further pregnancies. In Case No. 4 reduction of the inversion was undertaken from above, and was so easily brought about that this method is recommended in preference to Spinnelli's. In Case No. 5 reduction was also attempted abdominally, and required incision of the cervical ring posteriorly—a much easier approach than that per vaginam—which left a stronger scar. In conclusion, treatment of shock, rather than of inversion, is urged as of first importance. Abdominal operation may follow four to six weeks later. Delivery of a subsequent pregnancy would preferably be by Caesarean section.

348 Mandelstamm's Operation for Artificial Vagina

A. MANDELSTAMM (*Zentralbl. f. Gynäk.*, January 27th, 1934, p. 222) regrets that outside Russia no reports have been published of the trial of his modification of the large intestine technique of formation of an artificial for a congenitally missing vagina. He describes a further eight successful cases: the essential point in his method is that the gut, freed from the anus and mobilized, is implanted (into the vaginal introitus) before its section, which is accomplished through the dilated anal ring. The length of gut required is easily assessed, the danger of pararectal infection is diminished, and the operation field is free of clamps.

Pathology

349

Types of Bacilli in Diphtheria

D. T. ROBINSON and F. N. MARSHALL (*Journ. Path. and Bact.*, January, 1934, p. 73) have examined 542 consecutive cases and carriers of diphtheria received into the Monsall Fever Hospital from the Manchester area, and have endeavoured to correlate the type of organism isolated with the clinical severity of the case and its resistance to serum treatment. Of the 542 strains examined, 129 were of the gravis, 104 of the mitis, and 296 of the intermediate type, eight were atypical, and five consisted of mixtures of types. The intermediate type therefore constituted 54.6 per cent. of the strains, in this respect differing from the findings at Leeds, where only 5.5 per cent. were of this type. Of the gravis strains 65.1 per cent., and of the intermediate strains 63.8 per cent., were isolated from haemorrhagic, severe, or moderately severe

cases of diphtheria; on the other hand, only 25 per cent. of the mitis strains came from these types of case. The death rate in patients infected with the gravis type was 13.8 per cent., with the intermediate type 15.7 per cent., and with the mitis type only 2.6 per cent. Twelve cases of diphtheria occurred in Schick-negative reactors; eight of these were infected with the gravis and four with the intermediate type. Tests to compare the virulence of the three types were made on 311 strains by the subcutaneous inoculation of guinea-pigs with 10,000 million organisms. While 96.9 per cent. of the gravis and 94.1 per cent. of the intermediate strains proved virulent, only 80 per cent. of the mitis strains did so. Moreover, the organisms were recovered from the heart blood of the guinea-pigs in 44 per cent. of the gravis and 45 per cent. of the intermediate type, but from only 22 per cent. of the mitis type infections. The authors state that the classification of diphtheria bacilli into the types already mentioned presented little difficulty, and conclude that the gravis and intermediate types are more frequently the cause of severe and fatal infections than the mitis type. Mitis infections are rarely fatal except in complicated cases, and are readily controlled by serum therapy; many gravis and intermediate type cases are resistant to serum, even in very large doses.

350 Occult Infection by *Leptospira icterohaemorrhagiae*

According to figures quoted by J. TROISIER, M. BARIÉTY, B. ERBER, and P. GABRIEL (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, January 22nd, 1934, p. 26) serological tests have pointed to infection by *Leptospira icterohaemorrhagiae* in horses, monkeys, and sewer rats both in Paris and in Fribourg. Agglutination against the organism of Inado and Ido in titres of 1 in 10, 1 in 50, and 1 in 100 was noted in the serum of a Parisian patient who for many years had spent much time in and under the water of swimming baths, but showed no signs of jaundice. In typical spirochaetosis, agglutination was noted in dilutions of 1 in 1,000.

351

Filterability of Tubercle Bacilli

A. W. DOWNIE and GERTRUD MEISZNER (*Zentralbl. f. Bakt.*, January 31st, 1934, p. 465) report the results of an extensive and very careful investigation into the possible existence of a filterable stage in the development of the tubercle bacillus. Preliminary experiments showed that the ordinary bacteriological filters could not be relied upon to keep back all acid-fast bacilli. With Berkefeld V candles acid-fast bacilli could frequently be demonstrated both microscopically and culturally in the filtrate. Berkefeld N candles were considerably less porous, and though occasionally permitting control bacteria such as *B. prodigiosus* or *V. percolans* to pass through, they were generally successful in holding back tubercle bacilli. Chamberland L2 candles occupied an intermediate position. Guinea-pigs inoculated with Berkefeld V filtrates frequently developed tuberculosis, usually of a local, but sometimes of a generalized, type. Only one Berkefeld N filtrate produced tuberculosis directly, but in another filtrate tubercle bacilli could be demonstrated by passage through a second guinea-pig. Chamberland L2 filtrates not infrequently gave rise to lesions in guinea-pigs, the tuberculous nature of which could be proved only by further passage. Experiments with culture filtrates and suspensions of tuberculous tissue, carried out by Ninni's technique of direct intraglandular inoculation, or by Van Deinsse's technique of intraperitoneal inoculation following on a previous injection of sodium phosphate, failed to call forth the appearance of definite macroscopic lesions or of acid-fast bacilli that could be shown to be real tubercle bacilli. The authors conclude that there is as yet no satisfactory evidence to prove the existence of a filterable stage in the development of the tubercle bacillus. The lesions observed are either (1) those of definite tuberculosis demonstrable in the inoculated animal or in passage animals, or (2) glandular and splenic enlargement whose tuberculous nature has not yet been demonstrated. It seems probable that these lesions are due to toxic substances in the filtrate or to other non-specific causes.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

352 Contraindications to Vaccination

W. BLACHER (*Jahrb. f. Kinderheilk.*, February, 1934, p. 26), who records four illustrative cases in children, maintains that special care should be taken in the choice of subjects for primary vaccination. Attention should be paid not only to the present condition, but also to past diseases. If it is suspected that such a disease as influenza, septic infection, or the like is not completely cured, the vaccination should be postponed from the spring to the autumn, or at least for a few weeks or months. In cases of latent tuberculous infection the vaccination should be postponed for one or more years, or until the time when the practitioner is convinced that the disease has passed the labile stage. The best method of avoiding this infection is to carry out vaccination between the fourth and sixth months. Children in a tuberculous environment require special attention. Owing to the liability to disease and tendency to allergic inflammation at that time the spring is not a suitable season for vaccination.

353 Therapeutic Incompatibilities

Discussing the question of therapeutic incompatibilities, F. EICHHOLTZ (*Med. Welt*, January 6th, 1934, p. 9) points out that the so-called "allergic" conditions may often be due to an injudicious combination of incompatible drugs. Every change in the mineral contents of the system, any disturbance in the interplay of the hormones, any modification of the metabolic processes, be they due to disease or to the administration of other drugs, can, to a very considerable extent, influence the effect of drugs. This has, he states, been shown by Bless with narcotics, by Schuntermann and Birch-Hirschfeld with digitalis, by Heinrich with analgesics, and by Weiss and Hoppe with local anaesthetics. Present experience shows that the greatest therapeutic incompatibilities may be expected where substances exercising catalytic influences are involved. Newer research has proved that x-ray therapy is no exception from the general rule of variable sensibility to drugs. By a new quantitative method, the author succeeded in measuring the biologic effect of x-ray treatment in tumour-affected animals, with the surprising result that previous administration of insulin enhanced the effect of x rays by nearly 100 per cent., while adrenaline not only counteracted this effect, but induced an increased growth of the tumour instead of the usual arrest of growth. Possibly this observation may explain why intensive x-ray treatment of the abdomen often has a damaging instead of a beneficial effect in tumour cases. Eichholtz comes to the conclusion that whenever certain measures cause a change in the "inner milieu" of the human system either through a modification of the mineral balance, through hormonal or metabolic disturbances, or through the simultaneous administration of drugs or toxic substances, such an organism will always react to the administration of any chemical substance in a manner differing from normal. In such circumstances the toxicity of even the best-known drugs may increase to a dangerous extent, and great care should be exercised in the simultaneous administration of several drugs, the combined effects of which are not sufficiently explored.

354 Suprarenal Cortical Extract in Myasthenia Gravis

M. ROCH, M. J. DEMOLE, and P. DUCHOSAL (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 5th, 1934, p. 113) record the case of a man, aged 19, who had suffered for two years from slowly progressing myasthenia gravis: a varied but ineffective therapeutics had included pituitary extract, whole suprarenal extract, insulin-glucose, glycochol, and hepatic extract. Rapid improvement followed three

courses of intravenous injection, given on ten successive days at varying intervals, of "cortigène," an extract of suprarenal cortex free from admixture with medulla; it was not only subjective but objective, for response to faradic stimulation of the biceps continued for six minutes after, but less than three minutes before, treatment. Since no signs suggestive of Addison's disease were present, the result is attributed to direct action of the cortical hormone on the musculature, activating oxidation, and facilitating synthesis of sulphydric bodies.

355 Aetiology of Bronchiectasis

P. JACCHIA (*La Pediatria*, February 1st, 1934, p. 173), in support of his hypothesis that some forms of congenital bronchiectasis are connected with changes in the germ plasm, reports the case of a boy, aged 14, who presented a deformity of the right external ear with occlusion of the auditory meatus as well as an almost symptomless bronchiectasis of the right lower lobe, which could only be congenital owing to the absence of any history of respiratory disease and the dilated and tortuous appearance of the bronchioles on x-ray examination. Jacchia also records the case of a boy, aged 14, with an ampullary form of bronchiectasis in both lower lobes and the right upper lobe, in whom there was a history of prolonged asphyxia at birth, which suggests some relation between diffuse bronchiectasis and delayed resolution of foetal atelectasis.

356 Irradiation of the Pituitary in Arterial Hypertension

P. L. DROUET (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 12th, 1934, p. 139) describes two cases in which a lasting reduction in blood pressure followed x-radiation of the hypophysis. Both patients were females. One had symptoms of hyperthyroidism and the other had been castrated. Signs of posterior hypophyseal hyperfunction were present, it was thought, in (1) the demonstration of a melanophorotropic hormone in the urine, (2) the visual fields—one patient had very marked retraction of the fields for red and green, the other a contracted field for white on one side and for red and green on both. Drouet quotes the finding of Cushing that hypersensitive subjects may have pronounced basophilia of the pituitary pars nervosa.

Surgery

357 Extra-articular Resection of the Knee

L. SARADINI (*Presse Méd.*, February 21st, 1934, p. 297) describes his technique for this procedure. The anatomy of the knee, here briefly discussed, shows that the joint can be excised without opening it. Its musculo-aponeurotic coverings are non-adherent, except at the condyloid attachments of the plantaris muscles. Section of these attachments reveals a plane of cleavage permitting of their detachment from the condyles and posterior surface of the capsule. The subquadriceps synovial cul-de-sac can easily be freed anteriorly from the quadriceps tendon and posteriorly from the femur. With the limb extended, an oval incision is made on the anterior surface of the joint, the upper curve passing just above the patella, the lower $1\frac{1}{2}$ cm. below the tibial plateau. The skin being raised, the femoral and tibial pre-articular teguments are detached. Along the upper cutaneous incision the fascia lata, vastus externus, quadriceps tendon, and vastus internus are severed from without inwards, the capsule not being entered. The upper ends of these are then separated to the upper limit of the synovial sac, which is plainly visible and is then detached from its adhesions. The femur is thus revealed, and, after pulling the quadriceps upwards and the cul-de-sac down, is sawn

perpendicularly to its axis at the upper part of the condyles. The muscles are then separated from the posterior articular surface. The limb being then placed vertically, with the sole of the foot on the table, the tibia is sawn from behind forwards, 1 cm. below the margin of the plateau. The patellar tendon is separated from the articular surface and cut level with the bone; thus, it is almost entirely conserved and forms a solid resistant plane in front. The tibia and femur are then brought into contact and kept in position with or without metallic sutures; the muscles, aponeurosis, and patellar tendon are joined with interrupted sutures, and the skin closed with a horizontal suture. The joint is thus removed *en bloc* without being opened and without the slow and always incomplete dissection of the synovial membrane and culs-de-sac of the classic operation. Notes of six cases are appended.

358 Gas Bacillus Infection of Urinary Tract

B. W. TURNER (*Urol. and Cut. Rev.*, March, 1934, p. 153) states that gas bacillus infection was first described by Maisonneuve in 1853, and sixty-five examples during the Crimean War were collected by Saïlerson. The cardinal symptoms of such infection are fever, local discoloration, and subcutaneous crepitation. Death is due to profound toxæmia from absorption of autolytic products of protein digestion in the wound, and to paralysis of the adrenals. Of fifteen previously recorded cases of gas bacillus infection of the urinary tract, nine developed after operation on the kidney, in six of which perirenal induration was present. Turner records two personal cases of gas gangrene, in a man aged 36 and a woman aged 30, following operations upon the kidney. The man, in whom the diagnosis was delayed and there was no x-ray treatment, died, while the woman, in whom the diagnosis was made early and x-ray treatment was given, recovered. According to the author, gas infection should be suspected whenever a high fever persists after operation upon the urinary tract.

359 Parathyroid Tumours associated with Hyperparathyroidism

E. CHURCHILL and O. COPE (*Surg., Gynecol. and Obstet.*, February 15th, 1934, p. 255) describes the alterations in the metabolism of calcium and phosphorus in hyperparathyroidism. The outstanding clinical manifestation is a generalized decalcification of the skeleton due to the inability of the bones to retain calcium. An increased excretion of calcium and phosphorus in the urine may cause a progressive calcification of the cortex of the kidney, and there may be calculi in the pelvis of the kidney. Other clinical signs may be bone tumours, fish-type vertebral bodies with kyphosis and skeletal shortening, fractures following slight trauma, and bone tenderness. Polydipsia, polyuria, general debility, constipation, and anaemia with leucopenia are other signs and symptoms of hyperparathyroidism. Eleven cases are reported in which an adenoma of one of the parathyroid bodies was present with the changes in calcium and phosphorus metabolism that are associated with an increased secretion of the parathyroid hormone. In only two of these cases was there any external evidence of a tumour in the neck. Operation was carried out in every case, and a benign tumour of the parathyroid body was removed either completely or by subtotal resection. The immediate result of the operation was a correction of the disturbance in calcium and phosphorus metabolism. The muscle and joint pains were promptly relieved. Convalescence was frequently associated with tetany, but this may be controlled by administration of calcium gluconate, irradiated ergosterol, and parathormone. All the patients made a good recovery with the exception of one who died following the removal of a ureteral stone several weeks after the primary operation. In one other patient the bones showed no evidence of increased density, and her fractures failed to develop callus. She was being treated by high calcium diet, vitamin C, viosterol, and calcium glycerophosphate.

Therapeutics

360 Chrysotherapy in Pulmonary Tuberculosis

A believer in the efficacy of gold salts in oily suspensions in cutaneous and pulmonary tuberculosis, H. MOLLARO (*Presse Méd.*, March 10th, 1934, p. 395) replies to Giraud's criticisms of this method. His results, previously published, are revised in support of his contention. From these he maintains that results are more stable and recurrences rarer with oily suspensions of gold salts than with aqueous ones. If immediate results are not obtained, later improvement much more frequently occurs with oily than with aqueous suspensions. The only inconvenience to the use of the former is the necessity of long intervals between each series. Stored for a long time and slowly absorbed, there is a risk, if treatment be recommenced too quickly, of exposing the patient to accidents of sensibilization. If, however, the interval between each series is sufficiently long, the method is without danger and the accidents of late solubilization do not occur.

361 Complex Mercurial Diuretics

Of these, R. FLECKSEDER (*Zeit. f. Urol.*, 1934, Heft I, p. 32) prefers salyrgan or novurit to novasurol, and combines them with administration, before or at the same time, of ammonium chloride—5 grams and upwards in 120 c.cm. of flavoured water. Intravenous injection of salyrgan (in doses of 1 to 3 c.cm. or more of 10 per cent. solution) is preferable; in combination with 10 c.cm. cecbolin and 20 c.cm. 33 per cent. dextrose solution it has led, in cases of cardiopathy and portal stasis, to a daily diuresis of 6 to 8 litres, and in a case of contracted kidney with tricuspid regurgitation to one of 13½ litres. The intramuscular route is chosen when veins are inaccessible or thrombosed; salyrgan is given in the peritoneal cavity (with or without ascites) when a universal hydrops puts the veins out of reach and impedes absorption from a muscle. Oral administration, in doses of 1 to 5 c.cm. of 10 per cent. solution, may be carried on for many days, and in combination with ammonium chloride treatment is called for when other modes of administration have been refused or found only temporarily effective. The mercurial diuretics are useful not only in cardiopathic conditions, but also in portal obstruction, obesity with water retention, ascites from peritoneal tubercle or carcinoma, and pulmonary or cerebral oedema. They are contraindicated in advanced marasmus or cachexia, open lung tuberculosis with danger of bleeding, very grave degrees of heart weakness, peritonitis, intestinal stenosis or tenesmus, cholaemic states, and especially in nephritis and all uraemic or pre-uraemic conditions with a tendency to nitrogen retention. Their use also calls for care in renal sclerosis, prostatic hypertrophy, or hyperthyroidism. After tissue acidification by the ammonium chloride treatment the diuretic action of salyrgan is chiefly extrarenal: both dehydration of tissue colloids and increased permeability of the cell membrane are concerned, and possibly a diuretic combination of mercury and bile acids is formed in the liver.

362 Intravenous Animal Carbon in Infections

During the course of researches on immunity Coghlin of Montreal employed intravenous injections of animal carbon in various infections in animals. Of 738 thus affected all were cured, and the course of the disease was shortened by this therapy. The endothelial cells of the liver, spleen, and marrow were found to absorb part of the carbon particles, the remainder being ingested by the phagocytes (which rapidly increased) simultaneously with the bacteria. A single injection also cured a human case of furunculosis of eighteen months' duration. SAINT-JACQUES, also of Montreal (*Bull. de l'Acad. de Méd.*, January 30th, 1934, p. 169), has tested this treatment clinically, and records the results in 100 cases of various infections (acute and chronic metro-salpingitis, acute puerperal infection, phlebitis, infected perineal tears, pneumonia and post-operative pulmonary congestion,

acute cholecystitis, etc.). Short notes are given of a few of these. With the exception of a case of acute articular rheumatism in which the pains alone were relieved, a case of polyarthritis which did not respond, and one death, all these cases were cured. The injections caused no reactions or ill after-effects. Saint-Jacques does not claim that this treatment is a universal panacea, but maintains that it is a valuable, effective adjuvant in the majority of cases of infection. He employs a 2 per cent. suspension of finely pulverized animal (not vegetable) carbon in intravenous (not subcutaneous) doses of 3 to 4 c.cm. In the majority of the above cases one injection sufficed for cure, though in the more serious six were necessary. The syringe and needle should be paraffined with liquid vaseline before being charged with the carbon, to prevent the piston sticking.

Dermatology

363 Treatment of Pruritus, Chronic Eczema, and Kraurosis Vulvae

B. KRIS (Wien. klin. Woch., December 8th 1933, p. 1490) recommends infiltration of the affected skin areas with a local anaesthetic for these complaints. Other writers have, he states, recorded good results from infiltration with physiological saline, 1 per cent. novocain or quinine-urea solution, while one author has introduced perineural anaesthesia of the pudic nerve. For nearly seven years Kriss has treated kraurosis and chronic eczema of the vulva and anus on similar lines by infiltration of the affected areas with 0.5 per cent. novocain or 0.2 per cent. tutocaine solutions. Excellent results are claimed in approximately fifty cases of vulvar and anal eczema. The technique is as follows: the skin is disinfected with benzene only; the syringe is fitted with a long needle which is introduced subcutaneously in the direction of the posterior commissure; in vulvar and anal eczema infiltration is carried out until the entire region is infiltrated and oedematous. The usual quantity of anaesthetic solution employed is approximately 2½ ounces. The first puncture is usually painful, especially around the clitoris and anus. No untoward complications have occurred. The majority of patients examined on the fifth day report that the chronic pruritus has subsided completely. The skin is softer and more supple; fissured hyperkeratotic areas assume a normal appearance, and blood supply improves. Should small traumatic haematomas occur, they disappear spontaneously. The author states that many chronic cases are cured by a single infiltration, but if the pathological conditions of some areas remain unchanged, further infiltration may be required after some weeks.

364 Eruptions following Gonorrhoea

S. J. SULLIVAN (Urol. and Cut. Rev., February, 1934, p. 93) states that four gonorrhoeal conditions of the skin were described by Buschke in 1899—namely: (1) simple erythema, (2) urticaria and erythema nodosum, (3) haemorrhagic and bulbous exanthems, and (4) hyperkeratosis or keratoderma blennorrhagica. Simple erythema is the most frequent, but is usually a forerunner of the other types. It is commonest over arthritic joints and next common in the inguinal regions. It is often seen during acute epididymitis and vesiculitis, or an acute exacerbation of chronic vesiculitis. Sullivan reports a case of haemorrhagic eruption in a man aged 35, in whom rapid recovery followed vasotomy. Hyperkeratoses are the most infrequent skin eruptions following gonorrhoea. Thick calcified plaques form on the palms and soles, as well as on other parts of the body. N. TOBIAS (ibid., p. 99), who reports an illustrative case, states that keratoderma blennorrhagica is a skin manifestation of an allergic reaction to the gonococcus. Pathologically the lesion is not primarily a keratosis, but a parakeratosis with many features of psoriasis, from which it must be differentiated. Tobias's patient was a man aged 34, who had recently had an attack of urethritis and presented arthritis of the

left knee and both ankle-joints and keratotic lesions on the forearms, wrists, penis, and soles. Repeated examinations of the blood and skin were negative for gonococci. The eosinophil count was 11 per cent., which was suggestive of an allergic basis. Considerable improvement followed immobilization of the affected joints and treatment by gonorrhoeal vaccine therapy.

365 Infra-red Photography of Subcutaneous Veins

H. HAXTHAUSEN (Brit. Journ. Dermatol. and Syph., December, 1933, p. 505) has found that infra-red photography has a useful clinical application, serving to demonstrate the presence of varicose changes in the small and medium-sized veins which elude direct observation or photography in ordinary light. Normally, the medium-sized veins which connect the great saphenous vein and its tributaries, and form with their many anastomoses a network under the skin around the entire leg, are rather slender vessels, running a straight course, and without any marked dilatations or other changes in calibre. The differences from the normal revealed by infra-red rays consist of a thickening of these vessels, irregularly localized pouchings of their walls, and a winding and twisted course. Such varices presumably play a pathogenic part, in at any rate some cases of ulcer and eczema of the leg, similar to that played by the large varices of the saphenous veins. Infra-red photography of these patients showed in some instances the unexpected presence of varicose conditions of the smaller veins, even when there was no varicocity of the larger ones. When the ulcer or eczema was unilateral, the varices were nearly always more pronounced on the affected side. The author urges the further application of this method in the investigation of the smaller subcutaneous veins.

366 Liver Treatment of Psoriasis

T. GRÜNEBERG (Derm. Woch., December 23rd, 1933, p. 1793) agrees with Spiethoff that administration of liver greatly diminishes the tendency to recurrences of psoriasis. He finds in addition that in irritative cases of psoriasis, which in response to applications of even indifferent ointments show itching or acute inflammation and exudation, a few weeks' hepatotherapy will enable ordinary local treatment to be applied effectively. On psoriasis in general, liver treatment, although occasionally brilliantly successful, appears to have an effect not superior to that of arsenic, manganese, or gold. Grüneberg suggests that the liver may act partly by increasing the sulphur (glutathione) content of the skin: he finds it most effective when accompanied by artificial-light applications of strictly moderate intensity.

Obstetrics and Gynaecology

367 "Elective" Treatment of Carcinoma of the Cervix

F. V. MIKULICZ-RADECKI (Zentralbl. f. Gynäk., January 6th, 1934, p. 13), avoiding as relatively unimportant the old comparisons between operative and radiotherapeutic treatment of cancer of the cervix, concludes in favour of "elective" treatment. In this some cases are operated on, but not all "operable cases"—only those which seem well suited. In operative cases radiotherapy is employed after and sometimes before operation. Other cases are treated by radium and x rays only. A combined statistical report is given of 5,500 cases treated on "elective" lines at eleven clinics. Operation, and usually post-operative x-radiation, was done in 35 per cent. With the exception of 5 per cent. untreated incurable cases, the remainder had radiotherapy only. Five years' cure was attained in 24.5 per cent., in some clinics in as many as 36.5 per cent. (Stoeckel): this general average of cure is stated to be higher than those previously reported for large series. Some 20 to 40 per cent. of cases required hysterectomy. The author's conclusions are as follows. Simple hysterectomy is to be rejected in favour of the extended opera-

tion: this is preferable as removing more paravaginal, parametrial, and pararectal tissues, not as removing iliac and hypogastric glands, for the vaginal and abdominal routes are equally effective in the end. It follows, since the vaginal operation has much less risk of infection and a much lower mortality rate, that it is preferable. Routine post-operative x-radiation is possibly useful, and should be done; post-operative radium treatment, with intraparametrial or rectal application, has a place in treatment of advanced cases. Pre-operative radiation has its scope in rendering cases operable, but wastes valuable time in those which are primarily suitable for operation. Its efficacy in diminishing infection is not yet proved.

368 Treatment of Primary Carcinoma of the Vagina

M. NIELSEN (*Ugeskrift for Læger*, January 11th, 1934, p. 47) gives an account of twenty-six cases of primary carcinoma of the vagina in three hospitals in Copenhagen. The first symptoms were, on the whole, those of cancer of the cervix, but what was distinctive of the vaginal disease was the average brevity of the interval between the first symptom and inoperability; only two of the twenty-six patients were operable when first seen. In as many as eighteen cases the symptoms had lasted less than two months before the first examination. As a rule, symptoms were not noted before ulceration of the lining of the vagina had begun. In addition to the two operable cases there were two borderline and twenty-two inoperable cases. Only thirteen were given combined radium and x-ray treatment. Among the twenty-six there were only four survivors, all of whom had been given combined radium and x-ray treatment. In two of these cases there was no sign of relapse after 2½ and 2½ years respectively. In the remaining surviving cases the observation period was still shorter. There were as many as thirteen cases in which treatment was followed by temporary improvement, which in two cases even amounted to the apparently complete disappearance of the tumour. But in all these cases relapses occurred in two to eight months. The disease often reappeared in other parts of the vagina, at a considerable distance from the seat of the primary growth. The author's statistical survey of the literature of 334 cases of primary carcinoma of the vagina shows that, if a post-treatment observation period of at least five years be required, the recovery rate is only about 10 per cent., the results being equally good, or bad, for radium alone or supplemented by the x rays. The author concludes, however, that radiotherapy is superior to operative treatment in this field.

369 Trichomonas Vaginalis in Gynaecology

N. KISSLING (*Gynéc. et Obstét.*, February, 1933, p. 116) reminds gynaecologists that *Trichomonas vaginalis* is a frequent inhabitant of the vagina and a cause of chronic leucorrhoea which is overlooked unless it is sought for by the correct methods. The organism is recognizable in the hanging drop by its motility in various forms, sometimes flagellated. Culture is in beef broth, and staining by Gram, Loeffler's blue, or gentian violet. When this is the causative organism the leucorrhoea is not cured by the usual injections. The author finds no method successful except that of painting out the vaginal canal and cervix with 1 per cent. lotio hydrarg. perchlor., which is mopped off and followed by the application of 5 per cent. glycerin of borax. This treatment must be daily at first. It quickly brings relief, but the use of glycerin of borax must be maintained for several weeks—"ovules" can be substituted for direct application. Alternatively, one or two applications of mercurochrome, 5 per cent., can be followed by yaten 105 (Bayer) pessaries daily for at least a month, and for several months before and after the monthly period. A 100 per cent. success is claimed for the latter method. The symptoms of leucorrhoea due to this protozoon, while not distinctive, are as follows: greyish or yellowish-white discharge (sometimes greenish) which is frothy, liquid, and offensive, and accompanied by pruritus and discomfort. It may be associated with any other organisms, and is occasionally found in the virgin vagina.

Pathology

370

Prediction of Sex

An attempt to predict the sex of the unborn child is recorded by M. DAVIS (*New England Journ. Med.*, February 22nd, 1934, p. 421), who injects testicular extract intradermally into the mother in doses of 0.2 to 0.3 c.c.m. The reactions were arbitrarily classified as negative (no reaction); one plus (a red area 12 mm. in diameter); two plus (a red area from 12 to 20 mm. in diameter); and three plus (a red area with a diameter of over 20 mm.). The readings were taken in from four to ten minutes after the injection, and the reactions disappeared usually within a few hours. The injections were slightly painful owing to the stretching of the skin, but few complaints were made. A negative reaction indicated a female foetus, and the two and three plus reactions were obtained in the case of the children being male. The records of the one plus reactions were almost equally divided between male and female offspring. The findings of 136 cases giving relatively poor results, the tests were repeated with a testicular extract from which more of the extraneous matter had been removed. In a series of 534 new cases the results were better—namely, 85.1 per cent. correct. Of 294 diagnosed as males the result was correct in 82.3 per cent., while the corresponding percentage was 89.6 for females. Davis suggests that the mechanism of the test is based upon some form of allergic reaction. It is easy to perform, but further research work is necessary to improve its accuracy. Tests were made from the third month of pregnancy onwards.

371

Influenza Bacillus Meningitis

J. B. NEAL, H. W. JACKSON, and E. APPELBAUM (*John Amer. Med. Assoc.*, February 17th, 1934, p. 513) report their observations on 111 cases of *B. influenzae* meningitis with four recoveries which they have seen in the course of the last twenty-three years. The symptoms differed in no way from those of meningococcal meningitis. More cases occurred in the first year of life than in any other year (thirty-four), and more than half the total (sixty-two) occurred in the first two years of life; fifty-nine occurred in females and fifty-two in males, contrary to the distribution in meningococcal meningitis, poliomyelitis, and epidemic encephalitis; the incidence was highest in the last quarter of the year; primary infections accounted for sixty-eight (61 per cent.). Pathological examination showed severe toxic degenerative changes in the liver and kidneys, and bronchopneumonia was fairly common. Endocarditis and acute splenitis were occasionally found, as were also arthritis, peritonitis, and gastritis. There was no particular tendency to the development of adhesions or to the formation of abscesses in the brain.

372

Reversion of Negative to Positive Schick Reactions

P. FEUILLIE, P. THIRY, and C. BLANCARDI (*C. R. Soc. de Biol.*, 1934, cxv, 367) draw attention to the occasional occurrence of diphtheria in persons who have at some time previously given a Schick-negative reaction. In the Belfort epidemic of 1920 Vincent, Pilod, and Zoeller recorded four cases of this type in a total of 1,472 cases. Seeking an explanation for the phenomenon, the authors made observations on Army recruits. Schick tests were performed, readings were not made till the eighth day, and every reaction that was not certainly negative was regarded as doubtful, and the recruit was vaccinated with anatoxin. There were 246 subjects who gave a definitely negative response. Two months later they were retested, and no fewer than seventeen of them—that is, 6.9 per cent.—now gave a positive reaction. The explanation favoured by the authors is that, as a result of the entirely new conditions of barrack life with the extreme fatigue incidental to army training in those unaccustomed to it, the immunity tends to flag and the antitoxin titre falls. These results do not lessen the value of the Schick reaction. They show, however, that a negative reaction, though indicative of immunity to diphtheria at the time, cannot always be trusted to remain negative.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

373

Epidemic Vertigo

S. WATEFF (Deut. med. Woch., February 2nd, 1934, p. 167) gives an account of an epidemic of vertigo which began in Bulgaria in the autumn of 1929. He observed sixty-two male and eighty-four female cases under ambulatory conditions. There were twenty-one patients between the ages of 4 and 15, thirty-five between the ages of 16 and 30, fifty-two between the ages of 30 and 50, and thirty-eight between the ages of 51 and 75. There were seven cases in 1929, eighty-one in 1930, forty-two in 1931, and sixteen in the spring of 1932. The giddiness was most frequently felt only when the patient was lying down, notably when he turned his head or was about to get up. At the same time there would be a momentary, more or less complete, loss of consciousness. Headache was common, being most often localized to the back of the head. Epilepsy and hysteria could be excluded from the diagnosis, although several of the symptoms were suggestive of one or the other. The mode of spread of this epidemic indicated an infection, and its manifestations were reminiscent of those forms of epidemic encephalitis which have been described as rudimentary, atypical, or subacute. Professor Wateff is not, however, prepared to say whether or not this epidemic can be classed as some form or other of lethargic encephalitis.

374 Injury to Liver from X-Ray Examinations of Stomach

K. GERMER and A. MELLENGAARD (Ugeskrift for Læger, February 1st, 1934, p. 124) have conducted investigations which show that ordinary examinations of the stomach by the x rays disturb the functions of the liver, if they do not actually injure it, in a high proportion of cases. The material investigated consisted of eleven men between the ages of 26 and 56 and thirteen women between the ages of 16 and 62. All had been admitted to hospital on account of digestive disturbances due to such ailments as ulcer, cancer, gastritis, colitis, etc. One skiagram was taken in each case, in addition to three transilluminations. Altogether, 177 estimations of the liver-lipase content of the blood, 169 of the icterus index, 168 of the urobilinogen content of the serum, and 180 of the biliary acid and urobilinogen contents of the urine were made. These examinations showed that in 60 to 70 per cent. of all the patients the functions of the liver were disturbed. Similar observations were made on a member of the hospital staff who, for two or three months, had worked in the x-ray room, but always with protective coverings.

375

The Heart in Myxoedema

As the result of a careful study of thirty-five cases of myxoedema, in thirteen of which there were abnormal changes in the electrocardiogram, and a review of the literature, W. R. OHLER and J. ABRAMSON (Arch. Int. Med., February, 1934, p. 165) believe that the signs and symptoms are sufficiently numerous and distinctive to warrant the term "myxoedema heart." After the diagnosis of myxoedema had been definitely established clinically and by tests of the basal metabolism, radiograms were taken of the heart at a distance of seven feet, and electrocardiographic records were made. The specific alterations in the electrocardiogram were a decrease in voltage of all the complexes and a frequent inversion of the T waves in all the leads. Increased auriculo-ventricular conduction time was noted in some cases. These abnormalities were observable with few exceptions when the basal metabolic rate fell to a level of -25 or lower. Enlargement of the heart was frequently revealed by the x rays in cases with abnormal electrocardiograms. Sluggishness of the cardiac contractions was demonstrated by fluoroscopy. Thyroid gland extract proved to be a specific in these cases, the electrocardiogram and the size of the heart returning to the normal after its exhibition. In myxoedema there is no definite and regular height

of blood pressure; in patients with dilated hearts the pressure tends to be normal or subnormal. The authors found that thyroid therapy tended to decrease high blood pressures in their series, and to raise those that were low. Distant heart sounds and mild congestive failure were frequent clinical findings. The authors comment on the paucity of careful pathological studies of the heart muscle in myxoedema, and think that no definite explanation of the cause of the cardiac changes will be forthcoming until such studies are more numerous and detailed.

376

Sulfosin Treatment of Schizophrenia

J. RAVN (Nord. Med. Tidsskrift, January 27th, 1934, p. 106) argues that before any therapeutic claim can be established in connexion with schizophrenia, it is necessary to discount the mistaken diagnoses, the spontaneous recoveries, and the well-known tendency of schizophrenics to react to treatment by suggestion. He has drawn up a table in which the fate of 1,534 patients is analysed, with special reference to the proportion of cures and partial recoveries. In a second table he analyses in the same way 366 sulfosin-treated cases already published. He notes how closely the figures in one table correspond with those in the other. This comparison suggests that whatever good sulfosin may do it must be attributed to suggestion. Among the cases treated by Ravn himself was one in which tuberculosis broke out in connexion with the injections.

Surgery

377

Surgical Treatment of Diabetes

M. DONATI (Med. Welt, January 13th, 1934, p. 36) maintains that, although insulin therapy has done much to rob diabetes of its dangers, the fact remains that some cases do not respond to it, or may require auxiliary therapeutic measures to assist its effects. Such considerations, he believes, justify the attempts at a surgical therapy, based on the study of the relations between the nervous system and the internal secretion of the pancreas, as well as between the function of the pancreas and other endocrine glands—these attempts aiming not so much at a "cure" of diabetes as at the increase of carbohydrate tolerance and, if necessary, of insulin sensibility. Monolateral denervation of the adrenal gland, resection of one or both splanchnic nerves, extirpation of the coeliac ganglion, sympathectomy of the arteries supplying the pancreas, partial isolation and ligation of portions of the pancreas, grafts of pancreas substance, extirpation of the salivary glands, ligation of the parotid duct, and partial parathyroidectomy are cited by this author as attempts at a surgical treatment of diabetes, and are described in detail. He comes to the conclusion that, although it is not yet established for which categories of diabetics these methods are indicated, the carbohydrate metabolism of diabetic patients may be definitely influenced—that is, the carbohydrate tolerance and insulin response increased—by surgical methods.

378

Maggot Therapy in Chronic Osteomyelitis

J. BUCHMAN (Ann. of Surg., February, 1934, p. 231) emphasizes the difficulty experienced in the treatment of chronic osteomyelitis. Disseminated foci of infection and devitalized particles of bone and soft tissue are found enclosed by the rigid-walled cavities of the bones. These foci must be removed by radical bone surgery, care being taken to preserve the epiphyseal plates, the periosteal covering, and the circulation of the bone. There then remains a large cavity to be filled by granulation tissue, and this usually presents a serious difficulty due to unequal healing, which may result in well-formed scar tissue at the periphery with an unfilled bone cavity beneath. It is therefore necessary that successful treatment should consist of a surgical removal of all diseased

parts, some method of sterilization of the wound, and removal of wound discharges and sloughed-off tissue, and some agent that will produce even a rapid growth from the bottom up with complete filling of the bone cavity before the circulatory changes incidental to scar formation occur. It has been found that maggot treatment is the most satisfactory. The wound is actively sterilized by the maggots, which remove micro-organisms by ingestion, and the proteolytic activity of the maggot enzymes breaks down the wound discharges and sloughs into end-products, which are then consumed by the maggots. In addition to this, they succeed in irritating the wound sufficiently to stimulate rapid growth. By this method of treatment convalescence is reduced in length and failures and recurrences are said to be greatly diminished. Immediate healing can be obtained in two to three months. Two cases are reported which contrast the efficacy of treatment by the Orr method and by maggot therapy. It is claimed that by the latter method the character of the healed bone is more nearly normal than by any other procedure, as there is no residual sclerosis or rarefaction, but an actual re-formation of the bony parts.

379 Prognosis in Gastro-duodenal Perforations

G. DALAGENIÈRE (*Bull. et Mém. Soc. Nat. de Chir.*, February 10th, 1934, p. 216) draws attention to a sign which he has observed in cases of gastric and duodenal perforation—namely, the dilatation of the first part of the jejunum. A case is reported which first drew attention to this sign, and in which the patient died; after operation, from paralytic ileus. Operative treatment was carried out three hours after perforation and disclosed a very dilated and abnormal jejunum. It is not suggested that this abnormality is the cause of death, but that it is a sign which indicates the extreme gravity of the prognosis. A further five cases have been observed, two of which died from paralytic ileus following a general peritonitis. Both these cases presented a marked dilatation of the upper part of the jejunum at operation. The remaining three cases were of similar severity, and sometimes of longer duration, but no abnormality of the jejunum was noticed, and intestinal function was re-established after operation. It is suggested that dilatation of the first part of the jejunum is an early sign of paralytic ileus, and that this condition spreads downwards. A further instance is reported of a twisted ovarian cyst which was operated on six days after torsion. The patient was gravely shocked, and operation showed that the upper two-thirds of the intestine was dilated and without peristaltic movement, whilst the lower third was normal. In spite of strong saline injections the patient died forty-eight hours after operation from paralytic ileus. The conclusion is reached that, when the upper loop of the jejunum is normal in a case of gastric or duodenal perforation, the patient will make a good recovery, but when dilatation is present the prognosis is very unfavourable.

380 Polyvalent Antisera in the Treatment and Prevention of Surgical Peritonitis

E. SCHNEIDER (*Zentralbl. f. Chir.*, February 10th, 1934, p. 325) regards the use of antisera against the organisms causing peritonitis as a notable surgical advance. At the Heidelberg Universitätsklinik it is the practice, in operations in which purulent peritonitis (from whatever cause) is present, to give a polyvalent serum intraperitoneally, as well as intravenously, in combination with dextrose solution. The latter mode of administration is also adopted prophylactically after every major abdominal operation. The serum given, in accordance with the findings of M. GÜNDEL and F. SÜSSERUCH (*ibid.*, p. 306) that surgical peritonitis is in the overwhelming majority of cases a mixed infection, is active against *B. coli*, the anaerobic gas bacilli, and enterococci; the importance of the last-named is very considerable. Mortality from appendicitis and perforated ulcers has been considerably diminished, it is stated, by use of this serum.

Therapeutics

381 Intramucosal Autoserotherapy in Asthma and Allied Conditions

Subcutaneous or intradermal injections of autoserum (the Achard-Flandin method) have given good results in urticaria, hay fever, etc., but have proved ineffective in asthma, spasmodic coryza, etc. This technique aims at the patient's desensitization to autotoxins substances liberated by repeated shock. A. JACQUELIN and G. BONNET (*Presse Méd.*, February 14th, 1934, p. 249) believe that in certain conditions and in asthma without signs of sensitization to inhaled particles there exists an auto-sensitization of the affected mucosae to toxic products from a digestive, hepatic, or endocrine malfunctioning, or from cellular lysis. They therefore advocate intramucosal autoserotherapy in such conditions, and employ the following technique. The serum of 10 c.cm. of blood from an elbow vein is injected into the mucosa of the inferior turbinate or into that of the internal face of the nasal fossa. To avoid alteration of the serum this amount of blood withdrawn must not be exceeded, and further punctures must be made if necessary; the fresher the serum the greater its desensitizing power. The injection must be made deeply into the mucosa; intramucosal oedema appears if the injection is correctly made. Doses commencing with 2/10 c.cm. and increasing by 1/10 c.cm. to 1/2 c.cm. are given daily for twenty days. The injection is usually painless, and causes no inflammatory reactions. Results of this treatment have been previously published in 1932; notes on nine further cases are here given. Jacquelin and Bonnet claim that various grave forms of asthma and asthmatic states can be favourably influenced by this treatment.

382 Treatment of Soft Chancre

C. P. SCHOKKING (*Nederl. Tijdschr. v. Geneesk.*, February 17th, 1934, p. 773) records his observations on fifty-eight seamen (eighteen of whom had chancreoid only, thirty-one chancreoid plus buboes, and nine buboes only) who were treated by the Dmelcos vaccine, which consists of an emulsion of different strains of Ducrey's bacillus. Each case required on the average three injections of 1.4 c.cm. The average duration of treatment for the chancreoid and the buboes was reduced by eleven and seven days respectively, and in most cases complications could be prevented. In only one case was there a severe reaction, followed by an attack of jaundice. The vaccine, which should be given in small doses, is especially indicated in cases of chancreoid and buboes which do not heal readily under local treatment.

383 Typhoid Perforation

C. CASCO (*Semana Médica*, January 25th, 1934, p. 305), dealing with the aetiology, symptoms, and treatment of intestinal perforation in typhoid fever, notes 9,781 cases of this disease in which the average of perforations was 3.51 per cent. (Nacke, in 133 cases of perforation, found that the site was the ileum in 106, the appendix in fifteen, and the colon in twelve.) Perforation occurs as early as the first week and as late as the hundredth day, but it is most frequent about the third week. It may be very small and solitary, or it may reach the size of a five-cent piece, and as many as twenty-five perforations have been found in the same patient. Casco notes that the fall of temperature due to a haemorrhage is transient, and is quite soon followed by an ascent to a still higher point. The change of the blood picture from leucopenia to leucocytosis, if the latter be polynuclear, is, he states, a very valuable sign in the absence of any complication ordinarily accompanied by this phenomenon. Treatment must be early, and consists of opening the abdomen, under local or mixed anaesthesia, through MacBurney's incision, identifying the perforation with the very gentlest manipulation of the intestine, isolating with gauze, closing with an "N" suture of silk or linen if small (if large, with Connell and Cushing stitches, and not purse-string sutures), gentle, if thorough,

peritoneal toilet, and drainage. After-treatment consists in overcoming dehydration, attending to the heart muscle, and maintaining intestinal tone with "pitressin" and hyper-tonic saline for a few days, and then resuming the usual routine treatment. The prognosis of success following upon such an operation is affected by four chief factors: (1) the age of the patient (the percentage of successes among patients of from 6 to 15 years is double that of adults); (2) the stage of the disease at which perforation occurs, the first and second weeks and those of convalescence being the most fortunate; (3) promptness in surgical intervention (twenty-three out of forty-nine successes recorded by Cazin were operated upon within twelve hours); (4) simplicity and rapidity of the operative measures—hence the writer's recommendation of simple suture and drainage.

384 Serum Treatment of Tularaemia

L. FOSHAY (*Amer. Journ. Med. Sci.*, February, 1934, p. 235) records fifteen cases of tularaemia treated by intravenous injections of a potent specific serum prepared from a goat in doses varying from 5 to 26 c.cm. With the exception of one patient who was moribund on admission, all showed a marked and prompt improvement, even when the serum was given as late as the second or third month of the disease. The therapeutic properties of the serum were found to be closely related with its desensitizing action.

Radiology

385 Radiographical Control of Duodenal Ulcer Treatment

D. M. CLARK and M. J. GEYMAN (*Journ. Amer. Med. Assoc.*, January 13th, 1934, p. 107) discuss the value of repeated x-ray examinations in determining the response of duodenal ulcers to treatment and when the healing process has been completed. In gastric ulcers this mode of control is well known, but in duodenal ulcers it has been employed to a lesser extent, since the niche sign is the only pathognomonic evidence, and it is only possible to observe the niche in less than 10 per cent. of duodenal ulcers. With the introduction of the compression technique, however, the duodenum filled with barium can be clearly brought into view, and abnormalities can be noted. The authors report their reasons for believing that the disappearance of a niche, thus viewed, indicates a favourable initial response, but not necessarily that the ulcer has healed completely. Symptoms may persist for a considerable time after such disappearance, and, conversely, a patient may be quite free from symptoms and yet have a demonstrable duodenal niche. This is explained by the fact that, when the oedema and infiltration surrounding a healing ulcer subside and the crater becomes plugged with a bud of granulation tissue, the niche no longer retains barium, and is therefore not demonstrable radiologically. This probably occurs relatively early in the course of healing. There is a wide range in the amount of time required for disappearance of the duodenal niche. As a general rule these ulcers heal more slowly than do gastric ones. The characteristic bulbar deformity of the duodenum in ulceration certainly indicates that an ulcer is, or has been, present, but it has no relation to activity, and is of little or no value in measuring the response to treatment. The absence of this bulbar deformity does not preclude the possibility of active ulceration, for such a deformity may also be caused by spasm.

386 X-Ray Treatment of Malignant Disease of the Upper Respiratory Tract

ENGELMANN (*Deut. med. Woch.*, January 25th, 1934, p. 127) gives an account of the recent achievements of a radiological institute in Hamburg under the direction of Professor Holthusen, who was the first in Germany (1929) to apply the principles advocated by Coutard. According to these principles, the therapeutic superiority of radium over x rays observed in the past does not mean that the latter necessarily possess an inferior elective action, but that the dosage was inappropriate. Coutard has shown

that the action of x rays may be improved by spacing the dosage in such a way that small daily exposures of low intensity are given over such a long period that the total dosage is considerable. The statistical table Engelmann publishes covers the period 1929-32, and concerns eighty cases—carcinoma fifty, sarcoma ten, histological definition lacking twenty. Twelve patients did not complete the treatment. Six were given radium treatment for the primary tumour and later treatment with x rays for the enlarged glands. In sixty-two cases only x-ray treatment was given. Of the twelve patients given inadequate treatment none survived; of the six given radium and then x-ray treatment five showed no clinical sign of disease; while of the sixty-two cases given x-ray treatment alone twenty-nine showed no symptoms. Altogether thirty-four of the sixty-eight patients were clinically symptom-free from twelve to thirty-six months after treatment. All the fears as to the subsequent appearance of clinical symptoms due to the treatment have hitherto proved groundless. The author concludes that the x-ray treatment which has achieved these results must be regarded as very valuable in the case of carcinoma of the upper respiratory passages. He has also had certain successes with this treatment in malignant disease of the upper third of the oesophagus.

387 Rad'ography of the Chest

F. B. EXNER (*Radiology*, February, 1934, p. 236) discusses the relative value of stereoscopic and single films in the routine examination of the chest. He believes that the tendency in the United States to insist on stereoscopy as a routine is often inadvisable in view of the greater expense rendering it prohibitive in investigating early cases of tuberculosis or their contacts. He states that only rarely will a single chest film fail to show any lesion which would have been demonstrated by a stereoscopic pair, provided that the film is of good quality and is carefully studied by a competent radiologist. He has estimated that such failure will only occur in about 0.4 per cent. of pathological chests; his estimation was based on a series of 500 such cases. In routine tuberculosis surveys a considerable saving can be effected without any significant loss of efficiency by the use of the single film unless the particular circumstances necessitate so many re-examinations as to offset the saving in expense. The chief value of stereoscopy is derived from the ability it confers upon the radiologist to recognize at a glance three-dimensional relationships, to distinguish as artefacts certain shadows which appear in one film but not in the other, and to appreciate the relative change in the position of various shadows which permits images obscured in one plate to be seen in the other. Exner disputes the value of the three-dimensional image, but admits the help given by stereoscopy in evaluating shadows of doubtful significance observed at a previous single-film examination. Moreover, he does not think that any patient should be diagnosed as tuberculous on the basis of a single film unless the pathological indications in it are indisputable. The personal equation of the radiologist is another important factor, for the stereoscopic method probably requires more rather than less skill in interpretation to avoid error. Some can make more dependable diagnoses with the stereoscope. In consultant work, however, it is argued that some type of multiple-film examination is much to be preferred.

388 X-Ray Treatment of Vaccinal Reaction

E. BARLA-SZAEÓ (*Arch. f. Kinderheilk.*, December 19th, 1933, p. 1) employed irradiation with x rays in thirty-seven recently vaccinated children, who, with the exception of a child aged 7 years, were between the ages of 4 and 12 months. The application was made during the stage of formation of the areola, only one being given, except in very severe reactions, when it was repeated in two days. The result, as confirmed by observation on controls, was a rapid subsidence of the reaction and general symptoms, without interference with the attainment of complete immunity. The method is suitable for cases with an abnormally severe reaction, for sensitive children, and in cases in which unexpected intercurrent disease develops during the period of reaction.

Obstetrics and Gynaecology

389 Aschheim-Zondek and Friedman Tests Compared

From an analysis of the literature and their own experience with 546 Aschheim-Zondek and 566 Friedman tests, H. C. MACK and G. H. AGNEW (*Amer. Journ. Obstet. and Gynecol.*, February, 1934, p. 232) conclude that both methods have a high degree of accuracy as hormone tests of the presence or absence of pregnancy, the latter being slightly more reliable as well as more quickly and easily performed. In proved cases of normal pregnancy they obtained 97.3 per cent. accuracy with the Aschheim-Zondek test and 97.8 with the Friedman method. In patients in whom pregnancy was definitely excluded the authors obtained an accuracy of 98.5 per cent. with both procedures. They remark that in abnormal or interrupted pregnancy the result of the test should be interpreted in association with the clinical findings. A negative result signifies either a non-pregnant state or an interrupted pregnancy; a positive reaction strongly denotes the presence of living foetal elements, but, due to a temporary delay in elimination of the hormone, a recent interruption of pregnancy or a foetal death cannot be excluded. The authors add that in cases of hydatidiform mole and malignant chorion epithelioma the amount of hormone excreted is many times greater than that excreted in normal pregnancy. The persistence of positive tests after treatment of these neoplasms strongly suggests continued chorionic proliferation. It is added that, while the variations in the figures reported by different investigators may indicate some divergencies in technique, the chief reason for the discrepancies appears to be the interpretation of the results recorded.

390 Lipiodol Injections in Treatment of Sterility

G. K. F. SCHULTZE (*Zentralbl. f. Gynäk.*, January 20th, 1934, p. 180) points out that hystero-salpingography by lipiodol injection is of therapeutic as well as diagnostic use in certain cases of sterility. When both tubes are occluded treatment by forcible injection at high pressures, although recommended by some, is too dangerous to risk. In a series of 154 women in whom lipiodol injection showed one or both tubes to be patent at the outer end, about one-quarter afterwards bore one or more children; after deduction of cases in which more than five months intervened between treatment and conception, cases receiving accessory treatments, and those in which anti-conceptual measures had at some time been used, there remained twenty-one cases (13 per cent.) in which the hystero-salpingography and the loss of sterility appeared to be directly connected. In two of these cases abortion occurred; ectopic pregnancies (not included in them) numbered two only.

391 Placental Separation following Acute Infarct

R. A. BARTHOLOMEW (*Journ. Amer. Med. Assoc.*, March 3rd, 1934, p. 676) reports a case of abruptio placentae following acute placental infarct. Caesarean section was followed by staphylococcal septicaemia, but complete recovery ensued after blood transfusions from donors who had been immunized by daily injections of a vaccine prepared from the organism. The author deduces evidence from this case in favour of the view that abruptio placentae is the result of poisonous split products of placental protein, particularly histamine, elaborated during the autolysis of an acute infarct on the maternal surface of the placenta. He remarks that the case also illustrates the conditions warranting the employment of Caesarean section rather than slower conservative measures in the treatment of this condition, the ever-present possibility of infection following section even in a clean case, and the apparently life-saving value of blood transfusions, particularly from donors who have been immunized against the specific organism concerned. He suggests, therefore, that in such infected cases it would be advisable to recover the organism by blood culture as quickly as possible in the course of the illness, and to maintain the

patient's resistance as much as possible until suitable donors can be immunized with the specific vaccine. In the present instance it was noted that the injections from the immunized donors were far more quickly and lastingly effective than were those of the donors who preceded them. The author adds that such an infarct probably permits a concentration of histamine in the decidual sinuses; the subsequent dilatation and rupture of these causing extravasation of maternal blood and placental separation.

Pathology

392 Photodynamic Action of Methylene-blue on Fixed Rabies Virus

H. E. SHORTT and A. G. BROOKS (*Indian Journ. Med. Research*, January, 1934, p. 581) have successfully inactivated fixed rabies virus by making use of the photodynamic action of methylene-blue. An opalescent suspension in distilled water of the brain of a sheep, that had been killed in a moribund condition nine days after infection with the virus, was mixed with equal quantities of varying strengths of methylene-blue solution, and exposed in Petri dishes to sunlight. At intervals the mixtures were tested for infectivity by subdural inoculation of rabbits. Two control suspensions were used. One consisted of the same series of mixtures kept in the dark, the other of brain tissue suspensions mixed with an equal quantity of distilled water (instead of methylene-blue) and exposed to sunlight. The results were striking. Judged by the rabbit inoculations a decrease in the virulence of the suspension became evident in a 1 in 20,000 final dilution of methylene-blue in about five minutes. Very marked diminution was apparent in ten minutes with a 1 in 10,000 and a 1 in 200,000 dilution. After an hour all methylene-blue suspensions proved inactive, while the control suspensions were still infective. It is interesting to note that the inactivation occurred in spite of the presence of living tissue cells. Experiments are now in progress to ascertain the practical value of immunization by rabies virus inactivated by this method.

393 The Conversion of Typhus Strains

H. MOOSER, G. VARELA, and H. PILZ (*Journ. Exper. Med.*, February, 1934, p. 137) bring extremely important evidence to suggest that all typhus is derived originally from the rat. It has been previously shown that in Mexico strains of typhus virus isolated from human patients, though immunologically identical with strains of Old World typhus, differ from these in two main respects—namely, in the production, after intraperitoneal inoculation, of scrotal swelling in guinea-pigs with numerous rickettsiae in the tunica vaginalis, and of a febrile, often fatal, disease in rats, again with numerous rickettsiae in the tunica. The Old World virus rarely produces a scrotal reaction in guinea-pigs, and causes in rats only an inapparent infection. The authors now describe the isolation from a severe louse-borne epidemic of typhus in Mexico of viruses, some of which conform to the classical European type, while others are intermediate between the European louse-borne and the Mexican murine type. Working on the hypothesis that the typhus virus can multiply freely only in the presence of mammalian blood, and that the louse-borne type is more haemophilic than the murine type, the authors carried out experiments in which daily blood injections were made into the peritoneum of rats that had been inoculated with louse-borne virus. The results were very encouraging. It was found that by this method the louse-borne virus frequently acquired the ability to cause a scrotal reaction in guinea-pigs and a fatal febrile disease in rats. In other words, the louse-borne virus became indistinguishable from the murine type. These findings are critically discussed, and it is concluded that the rat is the real reservoir of the typhus virus, and that the virus found in epidemic European typhus is merely an adaptation to a man-louse-man cycle of the original murine virus.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

394 Prognostic Value of Diazo Reaction in Tuberculosis

J. MILLE (*Nord. Med. Tidsskrift*, January 27th, 1934, p. 102) has investigated the subsequent fate of all the patients who gave a diazo-positive reaction in the urine on admission to a sanatorium between 1916 and 1930. Every patient's urine was thus tested on admission, and when the reaction was positive it was repeated every month till it became permanently negative. Altogether 362 patients gave a positive diazo reaction. There were ten cases of pleurisy with effusion, 331 cases of pulmonary tuberculosis, and twenty-one cases of tuberculosis in other organs. From four to fifteen years after discharge, nine out of the ten patients with pleurisy were still perfectly fit for work. The results were very different where the diazo-positive cases of pulmonary tuberculosis were concerned. As many as 226 terminated fatally in the sanatorium, and only seventeen patients were fully fit for work from one to ten years after discharge. Yet this 5 per cent. of cures, in addition to a certain number of cases which became sputum-negative and partially fit for work, are enough to justify active therapeutic enterprise (an artificial pneumothorax or a thoracoplastic operation) even in the face of a positive diazo-reaction.

395 Aleukia Haemorrhagica

According to N. FIESSINGER, F.-P. MERKLEN, and G. BROUËR (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 5th, 1934, p. 98) aleukia haemorrhagica, as described by Frank in 1915, is a syndrome due to acute failure of both haematopoiesis and capillary-endothelial resistance; cognate with agranulocytosis, its clinical picture is dominated by fulminating purpuric phenomena. Two cases are recorded, characterized by diffuse cutaneous, muscular, visceral, and mucous haemorrhages. There was a rapidly fatal course, in spite of a transitory response to blood infusions, and a progressive leucopenia (2,000 to less than 200 white cells per c.mm.) in which leucocytes were chiefly affected. Aetiologically, an intoxication by benzol, arsenic, gold, or bismuth has usually been reported, but of the present cases one followed an apparently benign catarrhal jaundice, the other an attack of chicken-pox.

396 Disease of the Coronary Arteries

D. RIESMAN and S. E. HARRIS (*Amer. Journ. Med. Sci.*, January, 1934, p. 1) conclude that there is an actual and not merely a relative increase in the mortality from cardiac disease, and that degenerative processes are largely concerned in this. Syphilis is not a prominent factor, but the authors incriminate worry, over-indulgence in food and sexual relations, and tobacco smoking to excess. Above the age of 70 death from coronary occlusion is rare. In the differential diagnosis from angina pectoris important points are ascertainable from the symptomatology and electrocardiogram. In coronary thrombosis the pain begins during rest, behind the lower part of the sternum or in the epigastrium, and may not radiate, whereas in angina it starts during an effort, behind the middle part of the sternum, and radiates to the left shoulder and down the left arm. Dyspnoea is marked in thrombosis and rare in angina; the attack lasts for hours to days in the former, and only for a few minutes in the latter. In thrombosis, shock is present, and vomiting frequent, while the pulse is small and often rapid, the temperature raised, and the blood pressure lowered; the reverse is usual in angina. There are no characteristic electrocardiographic changes in angina, but in coronary thrombosis the QRS complex soon becomes slurred, or decreased, or widened, and the T wave in Lead I starts off high on the downstroke of the R,

with an initial upward deflection and a terminal depression. Coincidentally the S-T interval in Lead III is depressed and the T wave inverted. Similar though less characteristic changes occur in Lead II. During the succeeding days the T wave in Lead I and often in Lead II becomes deeply inverted with an elevated S-T interval, while in Lead III the S-T interval remains depressed, and the T wave becomes upright. The acute abdominal conditions which have to be distinguished from coronary thrombosis include gall-stone colic, mesenteric thrombosis, rupture of a peptic ulcer, tabetic crisis, acute pancreatitis, and diabetic acidosis. The authors do not recommend the use of digitalis in treatment unless there is auricular fibrillation or congestive failure. After the initial full doses of morphine such a cardiac stimulant as caffeine sodio-benzoate is advisable in full doses of 2 to 3 grains hypodermically. Prolonged rest subsequently is essential for about six to eight weeks.

397 Toxic Diphtheria

B. SCHIRWINDT (*Jahrb. f. Kinderheilk.*, January, 1934, p. 318) records his observations on 205 cases of toxic diphtheria observed in a children's hospital at Moscow during the year 1929. Nasal involvement was frequent, its maximal incidence (80 per cent.) being found in haemorrhagic diphtheria. On the other hand, involvement of the larynx and the lower respiratory tract was much less common, and was often not discovered on clinical examination. The most frequent complication of toxic diphtheria was renal involvement, which occurred in 67.4 per cent., and after exclusion of the subtoxic cases in 82 per cent. The most serious complication was myocarditis, which was found in 20 per cent. of the cases and proved fatal in 77 per cent. The prognosis was better in cases of myocarditis occurring after the third week. Examination of the blood pressure was of no essential diagnostic or prognostic significance in toxic diphtheria, but was only of secondary importance. Paralysis occurred in 24.4 per cent., and its most frequent time of onset was at the end of the second week. Toxic diphtheria was usually toxic from the first, but in some cases the toxæmia did not occur until the second or third week. The fatality of the toxic cases was fairly high—namely, 21.6 per cent., and after exclusion of the subtoxic cases 32.8 per cent. Death usually occurred in the course of the first three weeks and most frequently in the second week. Only a small proportion of the cases of toxic diphtheria were admitted before the third day of disease.

Surgery

398 Tumours of the Parotid Gland

S. STEIN and C. GESCHICKTER (*Arch. of Surg.*, March, 1934, p. 492), in discussing tumours of the parotid gland, point out the difficulty in determining the nature of the growth. Benign neoplasms of the parotid gland show signs of malignancy in that they frequently recur after excision, whereas the malignant tumours rarely develop distant metastases. A review is given of 241 parotid tumours which occurred in a series of 50,000 surgical cases. Of these 241 cases 17 per cent. were considered to be malignant. The majority of patients were between 20 and 45 years, with the highest incidence in the third decade. The average duration of the benign mixed tumours from the onset to the time of operation was eight years, whilst in the malignant group it was slightly over four years owing to the more rapid growth of the malignant type of tumour. In the latter group the chief symptoms were pain, interference with hearing or sight, and involvement of the seventh nerve, whilst with benign mixed tumours the most frequent symptom was gradual

growth with intervals of quiescence. Although pain occurs in both the mixed and the malignant tumours, in the former it is usually discomfort rather than pain, which is local rather than radiating. The benign tumours were of firm, rubber-like consistency, sharply circumscribed, and not attached. Malignant tumours were usually more diffuse and more often attached to the surrounding tissues. Enlargement of the cervical lymph nodes occurred in 31 per cent. of malignant cases, but in only 4.5 per cent. of benign tumours. It was found that malignant tumours were more common over the age of 45. The growths with basal cell features were more liable to recur after treatment. Surgical treatment and irradiation both have their place in the removal of parotid tumours. Small benign mixed tumours should be excised, care being taken to preserve the facial nerve. Malignant tumours should be irradiated first and later excised if they become operable and freely mobile, otherwise irradiation should be continued. Following excision in operable cases, interstitial irradiation may be applied to the tumour bed.

399 Treatment of Parotid Fistula

G. E. KONJETZNY (*Zentralbl. f. Chir.*, February 3rd, 1934, p. 243) describes two cases of chronic fistula following incision of a parotid abscess, with stenosis of the duct and secondary multiple calculus formation. In one case excision, cauterization, x-radiation, and denervation of the parotid had been tried without success. The parotid duct was sounded from the mouth, first by fine catgut and then by fine metal sounds: a specially prepared laminaria tent of 1 mm. thickness was then passed through the constriction and left *in situ* for eight hours, and the dilatation of the duct was completed by the introduction of another tent, a few days later, for five hours. Stones were now felt and removed, and after a few days' irrigation from the mouth through a ureteral catheter the fistula closed. In the second case opening of the fistula and removal of the stone did not cure the fistula, which, however, was healed three weeks after dilatation of the duct by laminaria sounds.

400 Surgical Treatment of Haemorrhage from Gastric and Duodenal Ulcers

M. FRIEDEMANN (*Münch. med. Woch.*, February 16th, 1934, p. 239) opposes in some detail the view that the acute haemorrhages from ulcers should in no case be regarded as indications for immediate surgical intervention. This view has been expressed by Schlecht, who states that the mortality of such intervention is very high, whilst the haemorrhage itself is rarely fatal. Friedemann quotes Finsterer as having shown that such haemorrhages do not in the great majority of cases stop spontaneously, and also that the danger of operation during, or soon after, the haemorrhage is inordinately great. The author also refers to his own published work in support of operative intervention. Operation has come to be more frequently recommended since the later methods of transfusion and better anaesthesia have been available. Two personal cases are quoted of acute haemorrhage which were treated expectantly with transfusion of blood, saline, sugar, etc. Both died, and post mortem it seemed reasonable to suppose that operation could have prevented the fatal outcome. In a third in which the course of events was exactly similar, an immediate operation was performed, and resection (Billroth II) carried out, transfusion being given immediately after the operation. The patient was discharged nineteen days later. Further cases are quoted in which success was attained by rapid operative intervention. Even when the actual ulcerated region is small there is, says Friedemann, no certainty that the haemorrhage will not turn out to be either very severe or even fatal. Emphasis is laid upon the necessity of anaesthesia which is not too depressing. The author used evipan and avertin, and local anaesthesia. Whilst not claiming that all cases of haemorrhage should be subjected to surgical intervention, the author emphasizes that the extreme view of some physicians as to medical treatment in all cases of haemorrhage from ulcers is dangerous.

Therapeutics

401 Surgical Tuberculosis treated by Finikoff's Method

A. D. PARIS (*Crónica Médica*, February 15th, 1934, p. 93), reporting twenty cases, of whom one died of air embolism, declares that Finikoff's method is the treatment of choice, but, unlike its originator, he declines to ignore the help of heliotherapy and climate. Ankylosis is no longer the end to be sought in the treatment of articular and peri-articular tuberculosis, and Finikoff does not endeavour to immobilize the joint except for very short periods during the acute phase, and when movement causes great pain. His theory is that sufferers from surgical tuberculosis are in a highly allergic or receptive condition, that the affected areas are decalcified, and that caseous lymph glands act as centres for the dissemination of Koch's bacillus and its toxins. To counter all this, he relies on massive doses of calcium chloride intravenously, intramuscularly, by enema, or by mouth, as a recalcifying agent, together with peanut oil mixed with 10 per cent. tincture of iodine, and given intramuscularly to increase the action of the lipolytic enzymes of pancreas, spleen, liver, lungs, and lymph glands, and thus dissolve the fatty envelope of the bacillus. With these he gives a diet as rich as possible in calcium salts, and quite acid-free. Calcium should, it is stated, be given for a full year after a cure has been achieved. In 160 cases Finikoff has had but six failures, and the writer suggests that some of these might have been successful had he adopted surgical measures and heliotherapy as adjuvants. The treatment is warmly endorsed by Delbet, under whom Finikoff has worked in Paris, by Aimes of Montpellier, and by Zalewski in Poland.

402 Sodium Thiosulphate in Chronic Arsenical Poisoning

A. WERNER (*Klin. Woch.*, March 10th, 1934, p. 381) reports on a case of polyneuritis resulting from chronic arsenical poisoning which was immediately and lastingly improved by intravenous injections of sodium thiosulphate. The author remarks that though the efficacy of sodium thiosulphate in the acute stage of metal intoxications is well known, the only case on record of a cure of chronic arsenical poisoning by its means is the one published by Halliday and Sutherland (*British Medical Journal*, 1925, i, 407). He proposes to investigate whether sodium thiosulphate has a similar effect in other chronic cases of metal poisoning with or without neuritis.

403 Treatment of Adder Bites

S. FREY (*Deut. med. Woch.*, February 16th, 1934, p. 240) reviews the experiences at his hospital in Königsberg, where thirteen cases of adder bite have been treated without one death. Ten of these bites were inflicted by the *Vipera berus* and three by the *Vipera prester*. Six of the patients were children between the ages of 8 and 13. In six cases, including two children, there were no general symptoms. They were severe in the case of a girl of 17 and a man of 30, and consisted of extreme collapse, vomiting, the passage of blood-stained stools, and cerebral manifestations. The therapeutic measures adopted before admission to hospital included ligation of the limb in six cases, sucking of the wound in three, the administration of large quantities of alcohol in three, and the application of compresses also in three. In two cases the wound had been excised and in one case it was cauterized. Potassium permanganate had been injected around the wound in one case, and only once had serum been given. In three cases no therapeutic tinkering had been attempted. In hospital the routine treatment consisted of immobilization with dressings, the injection of serum, and general measures. Discussing the literature, the author remarks that writers are more concerned with the giving of therapeutic advice than with the investigation of its value. He is profoundly sceptical as to the beneficial effects of sucking out a wound, excising it, and alternately tighten-

ing and loosening a bandage round the limb with the effect of letting the poison reach the rest of the body in waves. Cauterization and the injection of chemicals such as potassium hypochlorite and potassium permanganate should also be avoided, as these and similar therapeutic ventures are calculated to do the patient more harm than good.

Disease in Childhood

404

Empyema in Children

H. T. ASHBY (*Brit. Journ. Child. Dis.*, January-March, 1934, p. 1) states that empyema in children must always be considered with pneumonia, as it is rare to find an empyema at that age following any other disease. Empyema is often difficult to diagnose, but should always be suspected if the temperature does not settle after an attack of pneumonia, or if the temperature due to pneumonia is prolonged. Absolute or stony dullness to percussion is the most valuable physical sign. *Sympneumonic* empyema, which arises while the pneumonia is still active, commonly follows bronchopneumonia, especially during an influenza epidemic. It is always best treated by aspiration of the fluid at the earliest possible moment. Open rib resection can be done a week or two later when the child can stand the operation better. Metapneumonic empyema, which comes on more slowly, is a sequel of pneumonia, and is best treated by operation as soon as possible. In the case of empyema in infants the mortality from the usual open operation is at least 80 to 90 per cent. Aspiration alone is therefore indicated at this age, and should be done at intervals directly the cavity fills up. In pneumococcal cases optochin (22 mg. per kilo body weight dissolved in 2 oz. of water, with a few drops of diluted hydrochloric acid) should be injected into the pleural cavity and the process repeated, if necessary, two or three times.

405

Anorexia in Children

L. SCHALL (*Munch. med. Woch.*, November 17th, 1933, p. 1805) examining in some detail the aetiology and treatment of failure of appetite in children, draws attention to the lack of knowledge of the physiological basis of appetite, and discusses the alternative theories—mechanical, chemical, and nervous—which have been put forward. The first matter to be settled in a case of anorexia in a child is whether an organic cause underlies the symptom. He believes that the condition is often a manifestation of acute gastro-intestinal disturbances or a posterior rhinopharyngitis. Loss of appetite in pyrexial conditions is frequent, but is not a constant symptom. In conditions like pyuria, tuberculous bone fistulae, bronchiectasis, etc., where absorption of the products of necrosis or purulent processes occurs, anorexia appears in very severe forms, while a similar condition is also described in cases when, for one reason or another (epilepsy, diabetes, renal disease), one-sided diets are given. When it is decided that the anorexia is due to some psychological cause a very careful consideration of the history must be made. Not infrequently the symptom can be traced to errors in feeding—as, for example, too long a retention of a semifluid diet—or to actual laziness on the part of the child to initiate the act of mastication. This soon leads to an actual distaste for food in general, since such semifluid diet is seldom appetizing: application of force in such cases leads to a psychologically conditioned anorexia. Overfeeding in the earlier days is a common cause of later loss of appetite, the child frequently becoming autocratic in the acceptance of food. Among other abnormalities in appetite the author emphasizes certain (apparently) inherited tendencies to be repelled by definite types of food or methods of cooking. Schall states that in the treatment of the neurotic type of anorexia the abandonment of all force or scolding is a *sine qua non*; the diet offered should vary greatly, be stimulant to the appetite, and not be given in large quantities. Efforts must be made to

give the necessary number of calories in as small a diet as possible (fat:carbohydrate = 1:3). Good results are sometimes obtained with glucose and insulin. Drugs and suggestion may be useful, but best of all is a removal of the child from the family circle and its tensions.

406

Treatment of Erysipelas in Children

L. M. NIGHTINGALE and S. STARR (*Journ. Amer. Med. Assoc.*, March 10th, 1934, p. 761) have treated fifty-one children under 12 years of age suffering from erysipelas by ultra-violet rays. Of these, twenty-three were under the age of 1 year. They found that the results were better than those obtained by serum therapy. As with serum treatment, the earlier the ultra-violet ray therapy was given the better the results. There was no difference in severity observed between the facial and the body type of erysipelas, except that the genital type was usually severe. Among previously healthy children over 2 years of age the mortality was almost nil, and death when it occurred was due to complications, such as mongolism, pneumonia, and so on.

407

Acute Transitory Cerebral Manifestations

A. LEVINSON (*Journ. Amer. Med. Assoc.*, September 2nd, 1933, p. 765) observes that differential diagnosis and treatment of these conditions in children are very difficult. Cases occur more frequently during autumn and winter, and often at night. Onset is sudden, with fever, apathy, or convulsions. The child is drowsy or comatose; usually the neck is rigid, and the Brudzinski and Kernig signs positive. There may be facial paralysis, hemiplegia, or diplegia. Occasional rales may be heard in the chest, the throat may be red, and the tympanic membranes congested. Apart from cerebral symptoms, physical examination may give negative results. Diagnosis may be established in a day or two, otitis media or pneumonia may appear, or the patient may recover entirely. Levinson terms this syndrome "acute transitory cerebral manifestations." He has studied eighty children, of ages ranging from 2 months to 13 years, of whom 82 per cent. were boys. The acute symptoms persisted usually for one or two days, and then subsided. The underlying causes were pneumonia, upper respiratory tract infections, otitis media, pyelitis, and acute rheumatism. In three cases no cause was found. Blood calcium and phosphorus were normal; blood sugar was usually increased. The cerebro-spinal fluid was increased in amount and pressure. The cell count was usually normal and the sugar content increased. He states that a normal count indicates no meningeal reaction, and that a normal, or even high, sugar content does not exclude meningitis. In meningococcal meningitis respiration is normal or only increased slightly. Petechiae indicate meningococcaemia. In obscure cases spinal puncture should be performed, except during convulsions. No generalizations can be made about treatment, which is sometimes unnecessary. Intramuscular injections of 10 per cent. magnesium sulphate solution have relieved convulsions. Cerebral oedema is always present.

Obstetrics and Gynaecology

408

Relaxation of Pelvic Joints in Pregnancy

Combined work by obstetricians and orthopaedists, D. ABRAMSON and others (*Surg., Gynecol. and Obstet.*, March, 1934, p. 595), on relaxation of the pelvic joints in pregnancy is based on direct x-ray measurements of the symphysis pubis. Nulliparae and males showed no distinction, the average width of the symphysis for both being 4.4 mm. Multiparous women averaged 5 mm. with considerably greater variation. Parity was recognizable from irregular margins, and sometimes a cystic appearance at the tips of the pubes. Age and multiparity exercised no influence. Skiagrams of the pelvis in 111 unselected cases of pregnancy showed increase of 3 to 20 mm. (average 7.7 mm.). The symphysis normally widens by 3 to

4 mm.; but in 25 per cent. of all pregnancies the increase is greater and becomes pathological. Relaxation is shown to begin early and not to increase during the last two or three months—nor during parturition except with gross trauma. Recovery began in the first month post partum, and was complete in three to five months, changes in density and outline of the joint being left. Motility at the symphysis can be demonstrated by having one leg pushed up while the other is pulled down by an assistant, the patient being recumbent. Chamberlain finds no relaxation of the sacro-iliac joints, but takes pubic motility as an early sign of pregnancy. The cause of the relaxation is attributed to a hormone in the corpus luteum, named "relaxin" by Hisaw. Symptoms vary with the individual rather than with the degree of separation shown radiologically. These are: pain at the symphysis or down the thighs, usually worse on beginning movement after sitting or lying; and difficulty in walking. Sacro-iliac relaxation gives backache and pain localized over one or both joints. On palpation of the symphysis, tenderness or even a sulcus may be found, and localized pain on pressure over the sacro-iliac joints. Complaint is not usually made before the eighth month, and sometimes not till after delivery—hence the importance of routine examination for relaxed pelvic ligaments before and after confinement. For treatment, a simple type of webbing belt is recommended. This fits round the iliac crests and symphysis so as to press on the pelvic articulations only. Strapping might be substituted. During the puerperium a marked case is well restored by lying with a muslin sling round the pelvis and suspended from overhead poles.

409 X-Ray Treatment of Malignant Ovarian Tumours

MARCEL JOLY (*Bull. Soc. d'Obstet. et de Gynéc. de Paris*, February, 1934, p. 128) maintains that the place of x-ray treatment in ovarian cysts is (1) preparatory to operation, (2) to complete the destruction of a growth which may not have been extirpated successfully, and (3) to attempt prophylaxis after excision. He analyses a series of thirty-six cases. The primary treatment of a cyst should be surgical. Only after laparotomy and microscopical examination of the tissue can the diagnosis be established. Radiologically the type of growth is not important, because no correspondence appears between the histological type and radio-sensitivity (except for seminoma which are highly radio-sensitive) in the cases discussed. Nothing is known as to the determinants of radio-sensitivity. Empirically, the author finds that forms with ascites react best, but that the pseudo-myxomatous semi-malignant type is definitely radio-resistant. Surgical removal of a growth should be carried to its limits, always leaving the smallest possible amount of malignant tissue to be absorbed after irradiation, which necessarily involves the passage of toxic products into the blood stream. The sudden growth of metastases, though possibly due to lowered systemic resistance, may conceivably be the result of the dilatation of local capillaries, which is the first effect of irradiation. Probably almost all malignant ovarian tumours have passed beyond complete extirpation; hence the importance of x-ray treatment. The time for applying x rays is as soon as the operation scars have become resistant—that is, three weeks after excision of the tumour. If ascites has supervened, a small amount causes a favourable dispersion of the rays: sufficient to act as a screen must be removed by paracentesis. But the ascitic fluid itself becomes toxic as the effect of irradiation, so that paracentesis during or immediately after it is dangerous: in one case it was fatal. In any event the patient must be watched, and dosage regulated according to the general reaction.

410 Evipan Narcosis in Midwifery

According to C. HOLTERMANN (*Zentralbl. f. Gynäk.*, February 3rd, 1934, p. 287) evipan sodium, rightly administered in labour, is less likely to be dangerous than in surgical operations, because (1) less is required, abolition of reflexes not being necessary, and (2) the patients are young and healthy. It is the best method of securing brief narcosis, as for the termination of the second stage.

and it affects the child less than any other anaesthetic drug. Two cases which caused anxiety are described: in the first, dosage was too high and the patient recovered after artificial respiration, but the second case was lethal (from circulatory failure) in a patient with pyrexia and hepatic degeneration. In over a thousand other labours evipan narcosis was satisfactory and gave rise to no anxiety.

Pathology

411 Metabolism of Iron and Copper in Anaemic Rats

F. C. BING, E. M. SAURWEIN, and V. C. MYERS (*Proc. Soc. Exp. Biol. and Med.*, February, 1934, p. 619) rendered rats anaemic by feeding them exclusively on cow's milk. One group of five rats was then sacrificed; the stomachs and intestines were removed, and the iron and copper content of the carcasses was estimated. A second group of five rats received by the mouth daily supplements of 0.5 mg. of iron as pure ferric chloride. A third group of six rats received daily intraperitoneal inoculations of 0.5 mg. of iron; and a fourth group of five rats received by the mouth 0.5 mg. of iron and 0.025 mg. of copper as copper sulphate. In seventeen days the animals receiving iron by the mouth had increased their haemoglobin from an average concentration of 4.15 grams to 7.23 grams per 100 c.cm. of blood. The corresponding rise for the rats receiving iron intraperitoneally was from 4.03 grams to 12.92 grams, and for those receiving iron and copper by the mouth from 3.90 grams to 13.40 grams. From this it appears that anaemic rats given iron by the peritoneal route form haemoglobin at almost the same rate as those given iron and copper by the mouth. The animals were killed and the carcasses analysed. The copper content of the control rats and of those receiving iron by the mouth was 0.051 mg. and 0.061 mg. respectively, while in those given iron intraperitoneally it was 0.104 mg., and in those given iron and copper by the mouth it was 0.115 mg. The conclusion is that anaemic rats treated by direct introduction of iron into the tissues are capable of retaining a far greater proportion of the copper normally present in milk than are rats having iron only by the mouth.

412 A New Chemico-hormonal Pregnancy Reaction

E. CUBONI (*Klin. Woch.*, February 24th, 1934, p. 302) describes a new chemico-hormonal pregnancy reaction developed by him, for which he claims greater simplicity and ease of execution than for the usual biological reactions. He filters the urine of mares through a paper filter, added 1 c.cm. of concentrated hydrochloric acid to every 5 c.cm. of urine, and leaves the mixture in a test tube in a boiling-water bath for ten minutes. After cooling the tube in cold water, 6 c.cm. of benzol are added to the same quantity of urine and the mixture thoroughly shaken. The urine is then poured off and the benzol collected, allowed to settle, and passed through a paper filter. Of this benzol extract 3 c.cm. is dried by heating to 60° to 80° C., 0.80 c.cm. concentrated sulphuric acid is poured over it in the test tube, the whole heated for a few minutes in a water-bath of 78° to 80° C., and finally the results are observed. The reaction is negative—that is, the subject is non-pregnant—if the fluid obtained is of a reddish-brown, brown, or malaga-wine colour, and not fluorescent; while if the reaction is positive, the fluid shows a distinct green fluorescence with transmitted light. The whole process requires no more than 15 to 20 minutes. The reaction was tested by the author in 165 cases with the following results: eighty-six non-pregnant mares and thirty-eight castrated horses were all negative; thirty-five pregnant mares were all positive; two mares covered but not impregnated were negative; four stallions were negative. In addition to its simplicity the author claims, as a further advantage of this reaction, that it is not influenced by the addition of carboic acid as a preservative, and that even without such precautions filtered urine kept in a refrigerator may be used after a month and still give a distinct positive reaction.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

413 Mercury Inunction in Septic Infections

WIETVELDT (*Münch. med. Woch.*, February 23rd, 1934, p. 288) records remarkable successes in the treatment of various acute infections, following the inunction of ungu. hydrargyri, which he has used in whitlow, gluteal, tonsillar, and mammary abscesses, malignant tonsillitis, and diphtheria. Inunction—preferably with a steel spatula—should be continued until the skin becomes reddened, though not discoloured. The author also finds this ointment efficacious in incipient tonsillitis. A thick layer of it is spread over the neck twice or thrice a day, and covered with a dressing. He recommends internal administration of ten drops daily of 0.1 per cent. mercuric chloride. In diphtheria, he employs a similar dosage of mercuric cyanide. In epidemics, or when there is a shortage of serum, this is stated to be a valuable prophylactic treatment. In puerperal fever mercurial ointment should be spread over the whole abdominal wall with inunction over the posterior and lateral thoracic surfaces every second day. In the author's hands this treatment has proved very useful in pulmonary abscess, after evacuation. Wietfeldt describes the case of an army surgeon who pricked his thumb at a necropsy on a case of septicaemia. In thirty-six hours he had severe axillary lymphadenitis and a temperature of 103.2° F. Inunction treatment was adopted, and in four days he was convalescent, without incision. Good results are recorded in two cases of furuncle of the upper lip with high temperatures and signs of septicaemia. In one case of lactational mammary abscess rigors and evening temperatures persisted for a week after incision and drainage. Inunction of the entire dorsal region was followed next day by free discharge of pus from the incision. No untoward symptoms were observed after this treatment.

414 Apyrexic Mediterranean Fever

C. CONESA (*La Med. Ibera*, March 17th, 1934, p. 326), who records an illustrative case, states that this disease may occasionally be apyrexial. In cases of obstinate neuritis of which the aetiology is obscure and in which the possibility of syphilis can be excluded, the diagnostic tests for Mediterranean fever infection should be performed. Nervous manifestations are not infrequent and may occasionally predominate. The blood in Mediterranean fever shows a constant lymphocytosis, monocytosis, and more or less marked leucopenia. Conesa's patient was a man, aged 41, who had probably been infected by contact with diseased goats. In addition to the characteristic blood changes his principal symptom was intercostal neuralgia. Burnet's intradermo-melitin reaction and the agglutination test were positive, and rapid recovery followed intramuscular injection of "neo I.C.I. 930" (3 to 70 grams).

415 Coronary Thrombosis

H. EPPINGER (*Wien. klin. Woch.*, February 16th, 1934), reviewing this disease, states that in most cases coronary thrombosis occurs as the end-result of a previously established angina pectoris, and the characteristic pain and anxiety are in both conditions the outstanding symptoms. After dealing with the differential diagnosis, Eppinger states that in coronary thrombosis the pain may continue for many hours unabated, and that the patient may not react to large doses of morphine; in any case, large doses must be tried. Whereas in an attack of angina pectoris the patient will most often realize that rest is the best treatment and consequently will tend to remain immobile and even hold his breath, the reverse is the case with coronary thrombosis, where the subject develops dyspnoea and great unrest. Clinically, the heart may show nothing special; the lungs show, in those cases not rapidly becoming fatal, signs not unlike those of acute pulmonary

oedema, and if they are x-rayed they appear deeply shadowed as in severe cardiac stasis. The sputum is scanty and contains protein and cells. The longer the attack lasts the more likely is the patient to survive it. After the acutest stage is passed, fever sets in (? reabsorption of metabolic products) from the diseased myocardium, and may disappear only after a week or so. There also appears in nearly all cases a considerable leucocytosis. Pericarditis and pleuritis may follow. The electrocardiograph is of importance in diagnosing involvements of the conduction system, and hence myomalacia or fibrosis may occur in the heart without any reflection in the electrocardiogram. Thus a normal electrocardiogram does not exclude occlusion of a coronary branch. Recovery from an acute coronary thrombosis may be almost complete and the patient may later die of quite another condition. As regards treatment, the author mentions the usual methods, warns against strophanthus, speaks in favour of purine derivatives, and especially "corphylamin." Intravenous glucose injections in 20 per cent. solution (10 c.cm.) are recommended.

416 Prodromal Measles Angina

E. MAYERHOFER (*Zeit. f. Kinderheilk.*, February 19th, 1934, p. 42) describes two forms of prodromal measles angina—namely, an early form, which is rare and occurs four to eight days after infection, and a late form, which develops on the ninth to the twelfth day of the incubation period, but always before the appearance of Koplik's spots. Prodromal measles angina is often associated with pseudo-appendicitis. Prodromal measles angina, which had been previously described by C. Herrman in 1915 and Veilchenblau in 1933, is regarded by Mayerhofer as an allergic reaction affecting the lymphatic system of the buccal cavity, analogous to the angina which accompanies vaccination, serum sickness, leukaemia, and agranulocytosis. It is rather a misleading symptom than otherwise, and it is only in cases of an outbreak of measles, especially in institutions, that its real nature is likely to be recognized.

Surgery

417 Injuries to Articular Cartilages of the Knee

O. ALEXAN and S. FRIBERG (*Acta Chir. Scand.*, 1934, lxxiv, Fasc. IV-V, p. 319) discuss the treatment of injuries to the menisci of the knee on the basis of 186 cases operated on in a military hospital in Stockholm in the period 1914-32. Most of the patients were about the age of 20. The medial meniscus was involved in 160 cases and the lateral meniscus in twenty-six. In 135 of the medial cases there was a history of indirect trauma, and in twenty-three of these cases the primary trauma was hyperflexion. In seventeen of the twenty-six cases of injury to the lateral meniscus there was no history of trauma. The most characteristic sign of injury to the medial meniscus was locking of the joint, observed in 132 of the 160 cases. The authors attach no diagnostic value to the x rays, and what they consider most important in the differential diagnosis is knowledge of a fairly recently discovered disease—chondromalacia patellae—which often interferes with movements to such an extent that locking is imitated. The clinical manifestations of this common disease are well defined, and it is therefore apt to be overlooked only by those who have never heard of it. The operation the authors recommend for injuries to the menisci is resection, but not complete extirpation. Of 132 re-examined cases of medial rupture, 132 represented complete recoveries. In the remaining twenty cases the patients were quite able to work, but suffered from some local discomfort. As far as the re-examined medial rupture cases were concerned, no evidence of subsequent arthritis deformans could be found. It was, however,

demonstrable in two out of the twenty-four re-examined cases of injury to the lateral meniscus. Among these twenty-four ex-patients were nineteen who had recovered completely. The discomforts in the remaining cases were quite slight. It may therefore be concluded that the prognosis for injuries to the menisci treated by operation is good.

418 Static Electricity in Anaesthetic Explosions

According to H. SCHRÖDER and T. C. NEEFF (*Schmerz Narkose-Anaesthesie*, March, 1934, p. 103) explosions during ether administration are as frequent as in that of newer inflammable anaesthetics such as ethylene, and in the absence of an unguarded flame or heated cautery are explicable only by ignition from a spark caused by the presence of two bodies charged with static electricity of different potentials. The present writers feel that insufficient heed has been given to the warnings of Ritter and Rimarski (1928), and they have investigated experimentally spark production in an apparatus (in an insulated trolley) in which the issues of cylinders of compressed oxygen and anaesthetic gas were mixed. They come to the following conclusions. Spark production may follow from different electrical charges in an apparatus, its component parts, and/or the attendant persons. The differences are due chiefly to non-"earthed" apparatus being moved about, the movements of a personnel wearing rubber soles or silk stockings, and the rapid passage of gases through constricted tubes. An arid atmosphere favours production of faradic charges. The practical preventive measures to be taken in operation theatres (concerning these measures W. SCHULTZ—*ibid.*, p. 98—who describes a serious explosion during ether narcosis, agrees), consist chiefly in (1) effective "earthing" of the anaesthetic trolley, apparatus, and operation table; (2) use of good conducting rubber for connexion tubes; (3) "earthing" of the patient by efficient electrical connexion with a well-"earthed" operation table; (4) "earthing" of all persons in the theatre and wearing by spectators and personnel of conducting rubber shoes; and (5) avoidance of a dry atmosphere.

419 Osteochondritis Dissecans

F. CONWAY (*Ann. of Surg.*, March, 1934, p. 410) describes osteochondritis dissecans as a non-infectious process involving the articular cartilage and the subchondral region of certain long bones of the extremities. This process, by sequestration from the cartilage, produces a loose body. A series of ten cases is reported in which there were eight instances of the knee-joint being affected and two of the elbow. The aetiology of the condition is uncertain, but trauma, low-grade bacterial infection, mycotic embolus, and congenital predisposition of the femoral epiphysis are some of the causes suggested. The commonest site is the lateral aspect of the medial epicondyle of the femur, and the condition is more often seen in males than in females. The average age in the series reported was thirty. The loose body may be completely or incompletely detached, or may acquire a secondary adhesion to the synovial membrane. Its continued presence in a joint may bring about osteoarthritic changes. Early symptoms are indefinite and consist of a feeling of disability in the affected joint, but a later development, following the further sequestration of the fragment, is locking or catching of the joint, and synovial membrane involvement. Swelling of the knee is a persistent feature, and during this period lamellation of the fragment occurs by deposition. A radiogram is valuable in diagnosis, and presents a characteristic appearance. Treatment of osteochondritis dissecans is arthroscopy with the removal of the sequestered fragments. The most satisfactory time for intervention is during the stage of demarcation, before complete sequestration has occurred. Stress is laid on the importance of a forty-eight hours' preoperative skin preparation. In seven cases operation was carried out with complete success, convalescence was uneventful, and movement was started by the patient about the twelfth day after operation. The remaining three cases refused operative treatment, and were given radiant heat treatment with slight relief of symptoms.

Therapeutics

420 Prophylactic Immunization in Measles

Pointing out the unquestionable connexion existing between measles and tuberculosis—that is, the lessened resistance to tuberculous infection and the tendency towards the reactivation of a latent tuberculous process in the relative allergy induced by measles and persisting after the disease has passed—J. SURANYI (*Orvosi Hetilap*, February 24th 1934, p. 31) advocates the prophylactic treatment of this affection by passive immunization in every case of children suffering from active tuberculous processes, general debility, rickets, whooping-cough, scarlet fever, etc., if they are exposed to any danger of infection, or if an epidemic of measles occurs. The author recommends the intramuscular injection of convalescent serum taken from a measles patient on the sixth to the eighth day after the return of the temperature to normal. The dose is from 3 to 10 c.cm., according to the age and general condition of the patient. Children already suffering from other diseases require doses about 80 per cent. higher than those considered normal for their age. The best protective results are obtained if the immunization takes place before infection, while the incubation period offers less chances of complete protection, but even in such cases the process is much milder than if the child were unprotected. The duration of such passive immunity is about four to eight weeks.

421 Tannic Acid in Treatment of Pressure Sores

In addition to commending lead tannate dusting powder as a prophylactic against the development of pressure sores E. O. LATIMER (*Journ. Amer. Med. Assoc.*, March 10th, 1934, p. 751) advises the application of a freshly prepared aqueous solution of tannic acid to the developed lesions. The presence of infection is not necessarily a contraindication to its use, unless this is virulent and there is advanced tissue necrosis with bone involvement. If possible, treatment is begun before the skin is broken. The area and surrounding skin are cleansed, and all crusts, debris, and macerated skin removed. If a blister is present, the elevated epithelium is removed aseptically. Lesions that may be exposed to the air are sprayed hourly with the tannic acid solution, and, between sprayings the region is kept exposed to dry heat from electric lights or an electric hair drier. Wounds that must be dressed to be maintained clean, or to prevent direct pressure, are covered with sterile gauze which is kept saturated with the solution. The treatment is continued until a heavy coagulum has been formed. This usually requires about twenty-four to forty-eight hours. Afterwards no dressing is applied, nor is sterile gauze used to keep the coagulum clean and dry. Healing occurs as in burns, and as the coagulum separates at the edge it is clipped away. Should it be necessary to remove it prematurely, it may be softened with sterile paraffin. If a virulent infection occurs during this treatment, the crust should be removed and the lesion treated as an ordinary infected wound. The author reports that the results of this method were especially gratifying in lesions following cord injuries or occurring in bed-ridden diabetic patients, and in lesions under casts.

422 Symptomatic Therapy in Arthritis

J. L. KENDALL (*Med. Record*, March 7th, 1934, p. 245) reports good results in arthritis from "kiuma," a preparation first used at the Royal Mineral Water Hospital, Bath, by Watson in 1931, and containing a salicylic ester content of 15 per cent. Kendall agrees that this unguent relieves pain, inflammation, and swelling, and he adds that it also seems to promote vaso-dilatation. A type of shea butter (derived from the nuts of *Bassia farhin*) incorporated in kiuma probably has some specific effect. Nine cases are briefly described by the author. He first applies a pad soaked in chloroform to reddened the area and open the pores without blistering. The ointment is then rubbed in gently, and is quickly absorbed with speedy relief.

Ophthalmology

423 Operations for Detached Retina

In an extensive comparative study of the relative merits of Gonin's and Guist's operations for detachment of the retina, H. RIEGER (*Graefes Archiv für Ophthalmologie*, cxxxi, No 3, p. 410) analyses 101 unsuccessful cases on the grounds that these offer better possibilities of detecting mistakes, determining indications, and setting up prognosis than do successful cases. According to this author a reattachment of the retina following operation was observed in 21.4 per cent. of the Gonin and in 18.2 per cent. of the Guist cases. This proportion is certainly higher than the proportion of spontaneous cures. As to vision, 20.6 per cent. of the Guist and 6.7 per cent. of the Gonin cases showed definite improvement; no change was observed in 38.2 per cent. of the Guist and in 15.5 per cent. of the Gonin cases; worsening appeared in 41.2 per cent. of the Guist and in 77.8 per cent. of the Gonin cases. Amaurosis occurred after 26.5 per cent. of the Guist and 22.2 per cent. of the Gonin operations; the respective figures for complicated total cataract were 26.5 per cent. and 42.2 per cent. Complete loss of the eye resulted by atrophy of the bulb in 11.1 per cent., and by enucleation of the bulb in 13.05 per cent. after Gonin's operation, and in 17.6 per cent. after Guist's operation. The factors influencing the process were found to be: advanced age of the patient or of the lesion; extension of the latter; existence of multiple or extensive lacerations; restlessness or nystagmus of the patient. Under otherwise identical circumstances the forecast is dependent on the condition of the vitreous body. Myopes have comparatively favourable chances. This can be explained by the fact that in high-degree myopia the vitreous is either detached or extensively liquefied, in which case there is a better prospect of the inflammation induced by the operation resulting in a union of retina and choroid. That absence of the crystalline lens is an unfavourable factor is a well-known fact, and is probably due, in the opinion of the author, to the effect of the immediate contact with the aqueous humour of the vitreous.

424 Diagnostic Value of Tricoire's Reaction in Trachoma

M. A. EL-BAKLY and A. F. ABBASSI (*Bull. Ophthalmol. Soc. Egypt*, 1933, vol. xxvi, p. 61) describe Tricoire's technique as published in 1923. He obtained 100 per cent. positive results in trachoma. Belot, working with larger numbers, obtained 89 per cent. positive reactions in trachomatous cases and 43 per cent. positive in non-trachomatous controls. Mikaelian's positive reactions were 48 per cent. in trachomatous and 14 per cent. in non-trachomatous cases. The authors' experience has been similar. In the most acute types of trachoma the positive reactions did not exceed 54 per cent., while comparing all trachomatous cases with controls, the percentages were similar. The authors therefore conclude that the reaction has little or no diagnostic value.

425 Vision by X Rays

A. H. PIRIE (*Brit. Journ. Radiol.*, February, 1934, p. 111) describes an apparatus which enables the patient to see with closed eyes by the use of x rays. A complete x-ray outfit apparatus is used with an eyepiece, behind which is a transparent wheel having on it mounted lead letters forming words. These can be read through closed lids, since the x rays are perceptible by the retina. Among the possible uses listed by the author are the following. A patient with a foreign body in his eye can see it, locating it in two dimensions and with moderate accuracy in the third. Damage to the retina caused by a foreign body can be located by the patient. He can also distinguish between these two contingencies, and it is suggested that he might be able to detect a foreign body lying behind the eye, the rays being passed through the skull to the retina from behind. The condition of the retina can be ascertained in a case of complete cataract. The field of vision can be mapped out by the patient, and minute scotomata localized at once. A foreign body lying laterally to the retina can be made to cast its

shadow on the near side and on the far side of the retina, and the patient can thus be enabled to see two shadows—proving that the foreign body is outside the globe. The patient cannot recognize his own blind spot, as it is lost in the brilliant field of light which is seen. Pirie states that an examination lasting two minutes is quite safe, and well below epilation dose. A time switch, which runs for ten seconds, reminds the examiner of the quantity of rays entering the eye. In order to locate a foreign body or scotoma, or to map out the field of vision, a lead diagram, consisting of a cross with a perpendicular and a horizontal arm, is placed in front of the eye. This casts its shadow on the retina, dividing it into four quarters. The patient describes what he sees in each quarter. If a foreign body is present, casting its shadow into the upper and lower quadrant, the observer reports it in the inner and nasal quadrant. Finer subdivision for localization is obtainable by using a star with eight arms, and by having a lead circle, or even two concentric lead circles, to measure the distance from the centre of the retina. The depth of a foreign body from the front of the cornea can be roughly estimated by its change of apparent position when oblique rays are cast on the retina. It is suggested also that glass fragments might be localized by the fluorescence they set up in x rays.

426 Effect of Tryparsamide on the Eye

N. K. LAZAR (*Arch. Ophthalmol.*, February, 1934, p. 240) states that the literature from 1919 to 1930 only records transitory ocular changes. The writer found no ocular lesions in rabbits until large doses were used, and then only a mild reaction, which was by no means certainly due to the drug. In the post-mortem on a case of syphilis blind for some years, multiple organized foci of softening in the occipital cortex may have been due to the tryparsamide treatment. In thirty-two cases of syphilis of the central nervous system the central vision and fields were recorded before giving tryparsamide, and at weekly intervals during treatment. Five cases showed alteration in vision, two with permanent loss, and three with temporary constriction of fields and reduction in central acuity. These changes became apparent early in the treatment. If examination before the first three to six doses shows optic atrophy or constriction of fields, no tryparsamide should be given, or the course should be stopped for a period and sodium thiosulphate administered.

Obstetrics and Gynaecology

427 Dextrose Pessaries in Treatment of Leucorrhoea

According to E. KOTTLORS (*Med. Klinik*, February 23rd, 1934, p. 273), vaginal injections of dextrose assist in the treatment of leucorrhoea by (1) increasing the glycogen content of the lining membrane, (2) inducing hyperaemia, and (3) effecting some bactericidal action. Dextrose applied in pessaries is more effective than in solution. The pessaries are introduced (usually by the patient) at bedtime, the vulva and introitus being previously smeared with grease and an absorbent tampon being inserted subsequently. In the large series which Kottlors reports recourse was had at the same time to (1) general tonic treatment and exhibition of large doses of ovarian hormone where there was evidence of hypofunction, and (2) local treatment of existing cervical catarrh by cauterization, caustic applications, or abrasion of the cervical mucous membrane. The cases were non-gonococcal ones of various ages: they include diabetic subjects, those who had had total hysterectomy with vaginal drainage, and some examples of trichomonas infection.

428 The Obliquely Posterior Occiput Presentation

G. E. HUDSON (*Minnesota Med.*, February, 1934, p. 64) pleads for conservative treatment of the obliquely posterior occiput presentation. Weak pains should not be allowed to persist more than four or five hours, after which castor oil or quinine, or preferably both, should be given, a hot enema being of value. If this fails, or if the patient, after the four or five hours of weak pains, obviously needs a rest, she should be given 1/4 grain of morphine and a hypnotic.

Labour often follows naturally after such a rest. Through the first stage sedatives and food should be given, but the former must not be allowed to shorten the pains. Hudson waits until the pains are constant in interval and thirty-five to forty seconds in duration before administering 1/6 grain of morphine and 1/200 grain of scopolamine every four to six hours; provided that the pain lengths are as above and the cervix has not dilated more than 8 or 9 cm. The patient should enter the second stage of labour free from the influence of drugs, for it is only when the abdominal muscles are acting effectively that the majority of primiparae with an occiput in the obliquely posterior position can deliver the child without operative intervention. The author thinks that the value of food in sustaining the patient's strength has been overlooked, and favours small amounts of solid foods as well as fluids. In the second stage a Beck binder should be applied as soon as the cervix is fully dilated, since it often renders intervention unnecessary. If the occiput fails to rotate manual rotation is most likely to succeed. The patient may remain in the second stage for three hours, or even longer, provided that the foetal heart sounds are normal and the general condition of the mother is good.

429 Pregnancy Dermatoses

A. LYSANDER (*Zentralbl. f. Gynak.*, March 10th, 1934, p. 562) states that, apart from rare cases of herpes of gestation (identical, according to Buhring, with dermatitis herpetiformis), and the still rarer impetigo herpetiformis (a serious condition justifying induction of abortion), the very great majority of pregnancy dermatoses are morbid vascular (and especially vasomotor) conditions, such as erythema, exanthemata, urticaria, pruritus, and prurigo. Itching is a prominent symptom, and is not infrequently confined to the vulva: response to ordinary therapy is often disappointing, and it is then necessary to give protein injections. These originally took the form of serum from healthy gravid subjects, but other human or animal sera were found equally effective. Lysander reports thirty-one cases, twenty-seven occurring in the last two months of gestation; no fewer than sixteen had albuminuria, including two eclampsics. All were treated by intramuscular injection of small doses—for example, 1 c.cm. increasing to 3 c.cm.—of the patient's own blood, kept in a syringe about two minutes until commencement of coagulation. Two to three days' intervals separated the injections. The results were uniformly satisfactory, and the treatment is recommended as being free from danger of anaphylaxis and non-irritant.

Pathology

430 Resistance of the Cholera Vibrio to Phage

Y. N. YANG and P. BRUCE WHITE (*Journ. Path. and Bact.*, March, 1934, p. 187) have studied the relation between antigenic roughness in cholera vibrios and their resistance to the action of bacteriophage (Type A). They find that the smooth to rough transformation with *V. cholerae* is similar to that occurring in organisms of the Salmonella group, and involves a loss of the characteristic soluble specific substance, which is apparently of non-protein carbohydrate-containing nature. All intermediate stages between smoothness and complete roughness may apparently exist. The action of the A type cholera phage on a pure culture of *V. cholerae* is to destroy sensitive organisms and to leave resistant organisms untouched. These resistant organisms may consist predominantly either of smooth, intermediate, or rough serological types. Examination has failed to show any difference between rough phage-resistant types isolated by use of the phage and similar types isolated by special techniques not involving the use of the phage. For instance, by exposing a culture to a smooth cholera antiserum plus complement, it proved possible to kill off the smooth and leave the rough organisms. These rough organisms were indistinguishable from resistant rough strains isolated from phage-treated cultures. The conclusion reached is that in all probability resistance to

A type phage is not a modification induced by phage action, but is the result of selection of resistant elements present in the original culture.

431

Infectious Mononucleosis

W. ANTON (*Zentralbl. f. Bakt.*, February 28th, 1934, p. 89) has studied *Bact. monocytogenes*, the organism isolated originally by Murray at Cambridge from an outbreak of infectious mononucleosis in rabbits. He finds that, besides giving rise on intravenous inoculation to a typical increase in the blood mononuclears, it is capable, on simple instillation into the conjunctival sac of rabbits, of causing severe inflammation with involvement of the cornea. The possible aetiological relationship of this organism to infectious mononucleosis and glandular fever in human beings is discussed. In 1929 Nyfeldt isolated from the blood of a case of infectious mononucleosis an organism very similar to *Bact. monocytogenes*. No confirmation of his work has so far been forthcoming, but it is pointed out that blood cultures in naturally infected rabbits are almost uniformly sterile. The organism is most frequently isolated from the glands. The disease in rabbits presents many points of similarity with that in human beings, particularly in relation to the pathological findings of enlargement of the lymphatic glands, lesions of the spleen, and necrotic foci in the liver.

432 Therapeutic Action of Different Parts of the Stomach in Pernicious Anaemia

E. MEULENGRACHT (*Ugeskrift for Læger*, February 15th, 1934, p. 179) considers that the treatment of pernicious anaemia with stomach preparations should replace that with liver as the former is more effective and cheaper. Hitherto, the active principle in the stomach has not been identified, but the following investigations by the author show how greatly the potency of different parts of the stomach varies. Pigs' stomachs were dissected in such a way that the parts belonging to the cardiac, fundus, and pyloric areas were separated from each other. They were dried, defatted, and pulverized. After giving details, with numerous tables, of nine experiments, the author points out that fundus powder invariably proved to be inactive. Pylorus powder, on the other hand, was invariably potent, even to a high degree. The pyloric glands would therefore seem to be responsible for the secretion of the specific but hitherto unidentified anti-anaemic factor. As for the powder from the cardiac area of the stomach, the final verdict must rest in abeyance, as some of the patients on whom it was tested were unsuitable for the experiment, and some of the tests were still proceeding. But the technique of these tests having been worked out, the potency or lack of potency of the glands of the cardiac area of the stomach should be ascertained in the course of a few months. Already it can be claimed that the pyloric glands have a secretory function which is reflected in the vascular and the nervous systems, and which is essential to life.

433 Identification of *V. cholerae* by Fermentation Reactions

B. HEIBERG (*C. R. Soc. de Biol.*, 1934, cxv, 934) has studied the fermentation reactions of 375 strains of vibrios coming from various sources. Twenty different substances were used, but it was found that six groups could be established on the basis of sucrose, arabinose, and mannose fermentation. Groups 3 to 6 were easily distinguished from the true cholera vibrios by their failure to give the cholera red reaction. The strains of group 1, which were the most numerous, produced acid in sucrose and mannose in twenty hours at 37°C., but not in arabinose; 239 of these were agglutinated by a cholera antiserum, while twenty-seven showed no agglutination. In group 2 sucrose alone was acidified; one strain was agglutinated, while seventy-six strains failed to agglutinate with a specific antiserum. It would appear, therefore, that the rapid fermentation of sucrose and mannose and the failure to ferment arabinose is characteristic of the true cholera vibrio. While the use of these reactions cannot replace the agglutination test in the examination of unknown strains, it is, nevertheless, likely to prove of value in the identification of inagglutinable cholera vibrios.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

The "Rheumatic" Tonsil

434

C. DIAZ *et al.* (*Anales de Medicina Interna*, February, 1934, p. 143) have made an exhaustive research into the history of thirty tonsillectomized subjects, of whom twenty had suffered from rheumatism, and, after a series of control experiments on individuals with healthy tonsils, they conclude that the aetiological problem presented by tonsillitis has not yet been solved. They emphasize the importance of streptococcal foci in the tonsils in the evolution of rheumatic diseases. The parallergeric action of these foci causes recurrence and chronicity, and renders cure impossible even in the absence of any other toxic agent. In twenty of the forty-seven cases examined the infective germ was a haemolytic streptococcus. Non-haemolytic streptococci were found in ten cases, *S. viridans* in four, *B. coli* in two, and staphylococci alone or in combination with other organisms in the rest. They believe that it is impossible to differentiate the rheumatic from the non-rheumatic tonsil, but advise that when a haemolytic focus is present the tonsil should be removed, even though the endocardium is infected and the temperature is raised. In very septic cases with high temperature, positive blood culture, or asystolic signs, extirpation should be postponed. When the inflammation of the tonsil is great, but the temperature is not very elevated, and sedimentation not much accelerated, they advise enucleation, for a day or two previous to which salicylates by the mouth or acriflavine intravenously should be given. This should also be given on the day after operation. Risks of enucleation, when it is properly performed, are hypothetical. They had two cases of septicaemia following incomplete tonsillectomy, in both of which *Streptococcus viridans* was found to be the active agent. Hence they advise caution with regard to the operation when this organism is detected.

435 Indications for Nerve Blocks

Discussing the diagnostic, prognostic, and therapeutic applications of nerve blocks induced by injecting alcohol or procaine hydrochloride, H. S. RUTH (*Journ. Amer. Med. Assoc.*, February 10th, 1934, p. 419) indicates how a differential diagnosis may be made of the origin of abdominal pain, a particularly valuable result in cases of malignant disease. Nerve block has therapeutic value in such conditions as aortic aneurysm (when only two thoracic nerves have to be infiltrated), in inoperable malignant disease, tuberculous laryngitis and pleurisy, and in arthritis deformans, when associated with vascular changes and pale clammy cold extremities, and before the occurrence of severe bone involvement. Ruth draws attention to the delay that may occur before the full benefit of an injection is manifest; the time can be shortened by using full doses, but the escape of alcohol into the adjacent tissues must be avoided lest degenerative processes ensue.

436 Detection of Latent Tetany in Exophthalmic Goitre

D. W. C. NORTHFIELD (*Guy's Hosp. Report*, January, 1934, p. 118) has applied the minimal electrical stimulus test to cases of exophthalmic goitre in order to determine whether it is possible in this way to indicate cases which would undoubtedly develop frank symptoms of tetany after thyroidectomy. He reports that in this disease there is a marked diminution in the minimal electrical threshold stimulus of peripheral nerves, and that this diminished threshold is much improved by operation. In a young patient with a short history a low figure is to be expected, and is an indication in some measure of the severity of the condition. A low post-operative figure is also to be taken as a warning that further treatment may be necessary. When the disease has existed for a long time before relief is sought, this figure will probably

remain below the normal. Northfield is satisfied that a markedly low threshold (in the region of 0.6 mA.) constitutes evidence of latent tetany, and may lead to frank post-operative tetany. Hyperpnoea and pyrexia are considered to be the chief primary factors in producing latent tetany. The author concludes, therefore, that the alleviation of the former by complete rest and of the latter by adequate methods of cooling are the best means of preventing post-operative tetany. In the test the weakest galvanic current is determined which will evoke a muscular contraction. The brachio-radialis muscle is always used, and the conditions of moisture of skin and temperature which affect the contact of the electrodes are kept constant. In forty-one cases of exophthalmic goitre it was thus shown that the average threshold was 1.4 mA. instead of the normal of 2 to 3 mA.

437 Erythema Nodosum and Syphilis

P. EVRENIADIS (*Thèse de Paris*, 1934, No. 110) records nine illustrative cases in patients aged from 17 to 37 in whom erythema nodosum appeared in the course of secondary or tertiary syphilis. He maintains, however, that the coexistence of the two conditions does not prove the syphilitic origin of erythema nodosum, but merely indicates that the unknown pathogenic agent of erythema nodosum has been activated either by syphilis itself or by antisyphilitic treatment.

Surgery

438 Hydrotherapy for Stone in the Ureter

K. VOLKMANN (*Zentralbl. f. Chir.*, March 10th, 1934, p. 559) recommends for treatment of ureteral stone the method of Payr's Clinic, in which the patient, immersed in the bath, is given slow high rectal injections at low pressure; he also receives atropine or papaverine, and large amounts of tea. In thirty-four cases there were seven failures only; six cases are reckoned as successes in which after a bath the stone descended so as to be visible cystoscopically at the ostium and accessible to endovesical removal. Hydrotherapy, if successful, is usually so by the twelfth, but in Volkmann's experience occasionally up to the nineteenth, bath.

439 Recto-sigmoid and Sigmoid Surgery

H. B. DEVINE (*Aust. and New Zeal. Journ. Surg.*, January, 1934, p. 211) emphasizes the greater risk to the patient from operations on the distal half of the colon than from those on the proximal part. This is due to the poor blood supply in the distal segment, to its thin walls, and to the fact that in some parts the peritoneum is absent or fatty. In the most distal part of the colon the contents are semi-solid and infective, and the muscular contractions are powerful. A recto-sigmoid anastomosis which is rendered necessary after the removal of a lesion at the lower end of the distal colon or the recto-sigmoid junction is too dangerous to be readily undertaken. An operation has been devised which is a modification of the Paul type of partial colonic resection. By this method the peritoneum is not soiled, and as no sutures are used the anastomosis does not become infected. In ordinary circumstances the mortality is negligible, but the method of operation is not applicable to growths in the upper or lower end of the sigmoid, in the descending colon, or in the splenic flexure. The advantages of this method are that the operation is carried out on a distal part of the colon which has been aseptically prepared, rendered functionless, and is allowed to remain functionless until the anastomosis has completely healed. The distal segment of the colon is deprived of its function by the construction of a mid-colic anus. In the formation of this the spur should be about $3\frac{1}{2}$ inches long, and exactly at right angles to the axis of the bowel. The end of the

spur should be attached to the skin to prevent retraction and consequent soiling of the distal segment, and the artificial anus should be as small and neat as possible. A resection and anastomosis of the sigmoid may subsequently be performed without danger, as the bowel has no septic content, is devoid of peristaltic movement, and its walls are retracted and thick. The artificial anus can easily be closed. Three cases are reported in which this method of operative treatment was carried out successfully.

440 Primary Tumour of the Renal Pelvis

G. NICOLICH (*Zeit. f. Urol.*, 1934, Heft 2, p. 73) describes five cases of primary tumours of the renal pelvis, occurring in thirty-five years at Trieste, and constituting one-fourth of primary renal tumours: four were in males. In no case was it possible before operation to distinguish the pelvi-renal from a renal tumour, and "snowflake shadows" were absent on x-radiation. All the tumours were papillary, and three were histologically benign; yet in these three metastases afterwards occurred in the ureter, while one of the apparently malignant cases was cured by operation—so that histological criteria appear to be of minor importance. Nicolich concludes that in all tumours of the pelvis, nephro-ureterectomy is the operation of choice. Being a severe operation, it must be replaced in debilitated subjects by nephrectomy, which led to lasting cure in one case of the present series. Long after-care is necessary: one patient, three years after nephrectomy, had bleeding from papillary tumours of the ureter, probably present at operation. Secondary ureterectomy should be done, if possible, in such cases; if not, endoscopic electro-coagulation.

Therapeutics

441 Liver Extract Intramuscularly in Pernicious Anaemia

P. SCHULTZER (*Ugeskrift for Læger*, March 22nd, 1934, p. 319) has investigated in a hospital in Copenhagen the action on pernicious anaemia of a liver extract, "hepsol," prepared by the Danish firm—Medicinalco. This hepsol, which is an alcoholic extract of raw liver (1 c.cm. to every 5 grams of liver), was administered by intramuscular injection, which provoked neither a local nor a general reaction. The results were, on the whole, very encouraging, and the author concludes that this treatment is particularly valuable when the patients are very debilitated at the outset. It is not likely, however, that such intramuscular medication can effect more than does intensive treatment by the mouth. Several of the patients were at a later stage given an injection of 5 c.cm. of hepsol every fortnight, with the result that the blood picture continued to improve. In one case the interval between each injection was increased from a fortnight to a month, the dosage being raised to 10 c.cm. During an observation period of nine months there was no sign of relapse. It would seem from these observations that the anti-anaemic factor in the liver can be artificially stored in the body, which draws on its reserves according to its needs. Unlike insulin, the anti-anaemic factor does not apparently cause harm in large doses, even when given by injection; and there seems, therefore, to be no objection to the creation of such a depot in the body.

442 Cod-liver Oil Sensitivity

R. M. BALLYEAT and R. BOWEN (*Amer. Journ. Dis. Child.*, March, 1934, p. 529) report four cases of children in whom, owing to the addition of cod-liver oil to their diets, various types of allergic manifestations developed other than the one for which they first came for treatment. In one instance asthma, urticaria, and vomiting resulted, asthma and hay fever in another, asthma and eczema in the third, and diarrhoea with vomiting and urticaria in the fourth. The authors substituted carotene fortified with vitamin D in each case with entirely satisfactory results. The carotene was extracted with ether, thus eliminating all plant proteins. The added concentration of vitamin D

was such that ten drops of the mixture were the equivalent of three teaspoonfuls of ordinary cod-liver oil. On no occasion did untoward symptoms follow its administration.

443 Prophylaxis of Impetigo Neonatorum

W. H. GUY and F. M. JACOB (*Journ. Amer. Med. Assoc.*, March 17th, 1934, p. 840) describe the method adopted at the Elizabeth Steel Magee Hospital since 1930 for the prevention of impetigo neonatorum. As soon as possible after birth the infants are cleansed thoroughly with sterile paraffin. Each is then rubbed from the top of the head to the soles of the feet with 2 per cent. ammoniated mercury ointment before it leaves the delivery room. In the nursery daily cleansing is effected with cotton-seed oil, cotton balls and this oil being used for the buttocks and anus. Soap and water and powder are not employed. During the first few months of this procedure several cases of a more or less generalized chemical dermatitis were encountered. At that time 5 per cent. ointment was being used, and the complication was stopped by changing to the diluter form. No kidney irritation was found at any time. Whereas in 1929 there were thirty-four cases of impetigo at this institution in 2,344 births, there were only two in 1930, one in 1931 (when the prophylactic treatment was omitted), one in 1932, and none in 1933. The authors are satisfied that this simple and inexpensive method is worthy of adoption on a general scale.

444 Bilateral Artificial Pneumothorax Treatment

K. TÖRNING and N. F. MICHELSEN (*Nord. Med. Tidsskrift*, March 17th, 1934, p. 321) report from the Vejlefsjød Sanatorium in Denmark observations on fifty-four patients treated since 1925 with a bilateral pneumothorax. The chief object of their paper is to prove that even cavernous bilateral pulmonary tuberculosis is amenable to this treatment. In eleven cases it is still proceeding. The authors' analysis concerns the remaining forty-three, of which nineteen terminated fatally. Of the twenty-four survivors, nine derived no benefit from this treatment. The remaining fifteen patients were symptom-free and sputum-negative, as many as ten being fully fit for work. The successes achieved in these cases depended to a certain extent on the intrapleural pressure being kept so low that the retraction of the lungs was of a selective character, the healthy lung tissue being allowed still to function as well as it could under the circumstances.

445 Massage and Anaesthetic Injection in Muscular Rheumatism

R. BARANY (*Nord. Med. Tidsskrift*, March 10th, 1934, p. 295), the Austrian Nobel Prize winner, who has settled in Sweden, has during the past three years studied aseptic inflammation provoked by the injection of various saline solutions. He has also been in the habit of treating himself for muscular rheumatism, whatever its localization. The observations made on himself and others have led him during the past year to adopt a treatment which he has found effective in a variety of conditions other than muscular rheumatism. An area of pain or tenderness in the skin, or fascia superficial to a muscle, having been located, a subcutaneous injection of 3 to 5 c.cm. of a 1 per cent. solution of aethocaine or novocain is given at this point. After an interval of less than a minute for the tissues to become anaesthetic, they are vigorously massaged for half a minute. This combined treatment has proved effective in supraorbital neuralgia, and in the one case in which a relapse occurred after six weeks there was no obstacle to a repetition of the treatment. Itching in the ear, with or without eczema in the auditory meatus, disappears after one or two injections supplemented by massage behind the ear and towards it. In a case of chronic eczema of the fold of the elbow, hitherto refractory to treatment, rapid and striking improvement followed the author's treatment. Another patient was a man of 75, who showed a patch of skin as large as a hand, covered with crusts, at the back of one knee. This area was exquisitely painful, and the patient could hardly walk. The two skin specialists he consulted first recommended ointments and then resignation. The author, having noticed that his injections of saline solution

had reduced the sensitiveness of skin and promoted desquamation, gave his treatment in this apparently intractable case. Not only was the pain reduced but the sore healed. When it recurred five weeks later it was painless. The same treatment is also remarkably effective for huskiness in public speakers, and for the chronic cough and irritability of the upper respiratory passages after an attack of laryngitis.

Neurology and Psychology

446. The Amino-acids in Muscular Dystrophy and Atrophy

C. J. TRIPOLI and H. H. BEARD (*Arch. Int. Med.*, March, 1934, p. 435) record a study of the clinical and biochemical results following the oral administration of glycine and glutamic acid. In muscular dystrophies the creatine metabolism of the muscles becomes deranged, but investigations have shown that the administration of glycine increases the excretion of creatine by 40 per cent. The authors report results obtained by giving daily doses of 10 or 20 grams of glycine or glutamic acid to six patients with various dystrophies or atrophies. The average increases in the excretion of creatine ranged from 48 to 303 per cent., and in the excretion of creatinine from 11 to 46 per cent. Although at first the creatine formed was passed from the body in large amounts, it began to be retained in the muscles after a few weeks, and the patients then began to show clinical improvement. It appeared that the amino-acids supplied a deficiency in muscle metabolism. The creatine, retained as phosphocreatine, served over and over again to supply the energy for muscular contraction, and the muscular efficiency of the patient increased at a remarkable rate. When the therapy was discontinued the amelioration ceased and the patient began to revert to his previous condition. The authors think it possible, therefore, that the treatment should be continued for the remainder of life. The total number of cases of such treatment, reported by the authors and others to date, is 69, of which decided clinical improvement was observed in 51, and most obviously so in the muscular dystrophies. Only slight benefit was observable in cases grouped as progressive nuclear muscular atrophy. The administration of creatine was not found to be an effective measure. The authors suggest that patients with muscular dystrophies are not ingesting enough protein, or are not utilizing that ingested, or are not ingesting it in suitable form for muscle metabolism, or are suffering from some dysfunction of protein digestion which results in inability to utilize properly the ingested or formed amino-acids. They thus explain the success of amino-acid therapy in myasthenia gravis, pseudo-hypertrophic muscular dystrophy, and progressive muscular dystrophy.

447. The Argyll Robertson Pupil

J. Bussy (*Journ. de Méd. de Lyon*, March 20th, 1934, p. 237) deals with certain non-syphilitic conditions in which the Argyll Robertson pupil occurs. Duverger and Redslob have advanced several theories as to its pathogeny—namely, medullary lesions involving the cilio-spinal nerves (the opinion of Argyll Robertson himself); lesions of the junction between the sensory path and the nucleus of the third pair of nerves; lesions of this nucleus or of the nerve itself; lesions of the peripheral neurone lying either on the ciliary ganglion or on the ciliary nerves, with involvement and partial atrophy of the iris. In the following conditions the lesion is in undeniable relation with this pupillary sign: cranial traumatism involving the cerebral peduncular region; tumours in either the anterior quadrigeminal tubercles or the optic thalami; tuberculous meningitis; lesions of the orbit and optic nerve; lesions of the sensory nerves (ophthalmic zona); and lesions of the globe and ocular affections (glaucoma). In all these cases a unilateral (or predominant on one side) Argyll Robertson pupil is nearly always present. It has also been noted in encephalitis and certain infections due to undetermined neurotropic viruses. While cautioning against a too hasty diagnosis of a non-syphilitic origin

in these last conditions, Bussy, in view of our present knowledge of epidemic encephalitis and traumatism of the neuraxis, does not consider the Argyll Robertson pupil as a completely specific sign of syphilis.

448

Optic Neuromyelitis

R. A. PERRITT (*Arch. of Ophthalmol.*, March, 1934, p. 492) describes this rare disease as showing bilateral optic neuritis followed, after a variable interval, by myelitis. Sometimes only a retrobulbar neuritis is seen. Any degree of a rapid visual impairment to complete blindness may be present, while in 50 to 60 per cent. vision is more or less fully restored. The myelitis may, however, progress. In 75 per cent. of cases the optic neuritis precedes the myelitis by twelve hours to eighty-one days. While the fields may be variously affected, there is always a defect for red and green. Syphilis and nephritis are sometimes present, but most cases occur in perfect health. There is fatty degeneration and replacement of all or part of the optic tracts by neuroglia. Mercury, iodides, salicylates, strychnine, protein shock, and electrotherapy have all been tried. The disease differs from disseminated sclerosis in that the course is very acute, ending either in death or in practically complete recovery from the general and visual defects in 50 per cent. of cases.

449. Hyperpyrexial Treatment of Multiple Sclerosis

C. A. NEYMAN and S. L. OSBORNE (*Journ. Nerv. and Ment. Dis.*, April, 1934, p. 423) record the treatment of twenty-five cases of multiple sclerosis by hyperpyrexia induced by diathermy, radiotherapy, and the electric blanket. Considerable improvement was shown in 44 per cent., and a less but still definite degree of benefit in another 40 per cent. During a subsequent testing interval after treatment, ranging from a few weeks to eighteen months, all the patients remained stationary. Those selected for treatment showed predominantly the symptom of spasticity of the lower extremities, associated with loss of the abdominal reflexes, nystagmus, temporal pallor of the disks, and tremors of the trunk and extremities. The authors do not claim their results as indicating the success of the therapy, but rather as suggestions for further research. They point out that this form of hyperpyrexia permits accurate graduation of the doses of fever, and has none of the disadvantages of introducing chemicals or infections into the body. One fatality occurred, the patient being in the final stage of the disease, unable to move his arms or legs or utter sounds. The fourth treatment culminated with a temperature which suddenly rose to 108° F. In the evening he developed respiratory difficulties, which were followed by hypostatic pneumonia and death. The authors state that it is not easy to control the temperature in such advanced cases, and counsel great caution. In their entire series of diathermic treatment they only had two burns, however, both of which healed without complications. It is recommended that the heels of all patients should be padded with cotton, and a rubber ring placed under the buttocks, so as to avoid blistering.

Obstetrics and Gynaecology

450

Coagulation Diathermy in Gynaecology

A. BINET and J. MARCEL (*Gynéc. et Obstét.*, March 1934, p. 206) discuss the application of coagulation diathermy in gynaecological practice. A simple high-frequency apparatus is required, and suitably shaped electrodes. Coagulation is achieved by the passage of a current which blanches the part and leaves a pliable scar. If carbonization takes place destruction will be too deep. For surface destruction, a strong current for a short length of time; for a deeper penetration, a weaker current for a longer space of time, is the rule. In the cervix, bold application is rewarded by the best results. The slough separates in a week or two, and the patient need not be seen for a month, when another diathermy treatment can be given if required. Oedema, leucorrhoea, and a slight sanguineous discharge are to be expected, but not infection. Older women heal slowly, and

touching with silver nitrate may hasten separation of the sloughs. Douches, hot fomentations, ultra-violet light, and occasionally repetition of the diathermy may be required. Indications for diathermy. (a) in *vulva and vagina*, are: (1) benign tumours, especially urethral caruncle—if multiple, local anaesthesia enables a large area to be treated at one sitting. (2) leucoplakia, (3) skenitis, Bartholinitis, if subacute—gonococci are eradicated, (4) cancer of vulva or vagina—neoplastic cells are destroyed by fulguration, and growth excised by diathermy knife, with sealing of vessels; (b) *cervix*: (1) adenoma, (2) polypus, (3) stenosis—cured by conical electrode, followed by linear cauterization which produces soft distensible scars (for congenital cases this suffices, for cicatricial stenosis Hegar's dilators must be used subsequently), and (4) endocervicitis, the treatment of election—no anaesthesia, cure requires destruction of the cylindrical epithelium down to the muscularis (less than this induces deep cyst formation and Nabothian follicles). Here the electrode must be pushed through the internal os, which is often a reservoir of infection, then withdrawn to that level, and the current passed. The eschar may separate in a cast in a few days. Epithelium takes five to eight weeks to cover the area. Nabothian follicles and hypertrophic cervicitis are cured by needling. The external os may be corked by debris, which can be removed by forceps forty-eight hours after treatment. Contraindications are: near approach of the menstrual period, pregnancy, and uncurbed pelvic inflammation.

451 Maternal Mortality in Manitoba

F. W. JACKSON, R. D. DEFRIES, and A. H. SELLERS (*Canadian Pub. Health Journ.*, March, 1934, p. 103) record a five-year survey of maternal mortality in Manitoba from 1928 to 1932 inclusive, comprising 364 deaths, and with an average rate for the period of 5.1 per 1,000 live births. Data were collected by questionnaires, and replies were received for more than 90 per cent. of the series. The percentage distribution of deaths by major causes was: puerperal toxæmias, 28; puerperal sepsis, 25.3; abortions, 17.1; phlegmasia alba dolens and embolism, 9.3; and puerperal haemorrhage, 9.1. The safest age period for maternity appeared to be from 20 to 29, but race emerged as a factor in maternal mortality. The highest death rate occurred in primiparae, this being more than twice that in the case of women in their second and third pregnancies. One-third of all the deaths were not associated with a birth, and one-fifth were related to a stillbirth. A seasonal variation in the deaths from puerperal sepsis was observed, the rate being higher in the first and fourth quarters of the year. The maternal mortality rate for cities was estimated at 4.2; for towns of one to five thousand population, 7.1; and for the rural areas excluding such towns 5.5. For institutional cases it was 4.1, and for domiciliary cases 2.8. The corresponding figures for deaths from puerperal sepsis were 1 and 1.3. Only 23 per cent. of the patients received ante-natal supervision, the proportion of urban cases being twice that of the rural group. Nearly one-third of the patients (excluding those suffering from other toxæmias, abortion, and ectopic gestation) were only seen by a physician when the outcome was in grave doubt; poverty and ignorance were the two outstanding reasons for this.

452 Technique of Low Caesarean Section

H. FUCHS (*Zentralbl. f. Gynäk.*, March 17th, 1934, p. 610) states that of forty-three isthmo-cervical Caesarean sections, with curved transverse incision over the bead, delivery was effective manually in thirteen, by version in sixteen, by lever in ten, and by forceps in four. The risk to the foetus from intracerebral lacerations and bleeding is considerable. Such risk can be greatly diminished, and the ease of delivery is increased (together with lessened tendency to bleeding and escape of liquor amni into the peritoneal cavity) by combining the curved low incision with: (1) the initial application of Bonney's isthmus compressor, and (2) completion of the uterine incision after application of Willett's forceps to the foetal scalp, the bead being delivered by the same instrument with the aid of abdominal pressure.

Pathology

453 Demonstration of Tubercle Bacilli in Children following Gastric Lavage

N. LEVIN (*Svenska Läkarsällskapets Handlingar*, No. 1, 1934, p. 108) publishes as a monograph his studies, conducted in the Swedish hospital of Söderby, of the technique and findings of gastric lavage in obscure cases of tuberculosis. His material consists of 457 children, forty of whom were tuberculin-negative and who served as controls. In none of them were tubercle bacilli found in the contents of the stomach. The remaining tuberculin-positive children (417) were submitted to 680 such examinations, 249 of which proved positive (162 children with positive findings). After excluding from his further analysis the fifty-two cases in which no radiological examination was made at the time of the gastric lavage, the author confines his remarks to 365 children, 159 of whom yielded tubercle bacilli from the stomach. Of the three tests (direct microscopic examination of the sediment, growth on culture media, and guinea-pig inoculation), the first was found to be so faulty that little value could be attached to it. The second test proved very reliable, but the third was the most accurate of all. He states that it is indeed so decisively superior to the other two that it should never be dispensed with if reliable findings are required. But it should be supplemented by the culture test, for in twelve cases it, alone of the three, proved positive. If the absence of tubercle bacilli from the contents of the stomach is to be considered proven, gastric lavage should be repeated once at any rate, and preferably twice; and before it can be assumed that a positive has become a negative case, gastric lavage should thrice consecutively yield negative results at intervals of at least two months between each examination. After correlating the radiological findings with those of lavage, the author concludes that, at the present time, there is no other clinical-bacteriological examination which can compare in accuracy with gastric lavage for the discovery of tubercle bacilli in children suffering from early tuberculosis.

454

Puerperal Scarlet Fever

R. DEBRÉ *et al.* (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 23rd, 1934, p. 348) agree with Lemierre and Bernard that puerperal and surgical scarlet fever are identical with, and should not be differentiated from, the ordinary form of the disease, and that the scarlatiniform erythemas occasionally complicating puerperal infections are merely attenuated abortive forms of puerperal scarlet fever. Details of a case are given which substantiate these opinions. Typical scarlet fever developed in the hospital intern attending the case, and also in a patient in a separate building attended by this intern, and facial erysipelas developed in another intern in contact with the affected one. Attention is especially drawn to the laboratory findings. An erythrogenous streptococcus, of the type studied by the Dicks, was isolated from the lochia. Similar streptococci have been recovered from other infections. The authors have isolated them from the pus of a digital whitlow, and the Dicks have produced typical scarlet fever by rubbing a volunteer's pharynx with a streptococcal culture from a whitlow of a scarlet fever patient. As in all scarlet fever cases, the Dick reaction, with absence of antitoxin from the serum, was negative at the time of the eruption. The reaction of Schultz-Charlton (reaction of extinction) was positive, as in all cases of this nature. Only slight pharyngo-buccal symptoms were present, and streptococci were not isolated from the throat. The authors believe that a pharyngeal reaction and penetration of the germ at this site is of no significance in these cases; this point is discussed, experiments being cited. J. HALLÉ (*ibid.*, p. 353), discussing this paper, agrees that surgical and ordinary scarlet fever are identical. He cites such a surgical case, and relates the good results following the use of convalescent serum in these patients.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

455

Epidemic Myalgia

A. B. RICHTER and H. D. LEVINE (*Journ. Amer. Med. Assoc.*, March 24th, 1934, p. 898) record their observations on twenty-four cases of "epidemic pleurodynia" admitted to the Peter Bent Brigham Hospital, Boston, in July, August, and September, 1933. The ages ranged from 12 to 28 years. The sexes were equally affected. In most cases physical examination was entirely negative. In only one case was there a transient pleural friction rub. Most of the cases showed a high leucocyte count with polymorphonuclear predominance. The symptoms were similar to those described by previous writers. The treatment was that of acute pleurisy. All recovered.

456 Intestinal Parasites in Hospital Patients

R. WIGAND (*Deut. med. Woch.*, March 30th, 1934, p. 461) has studied in East Prussia the intestinal fauna of 1,330 hospital patients, 330 of whom were children under 14. The patients were classified according to the localization of their ailments. As far as *Ascaris lumbricoides* was concerned, 13.3 per cent. of the skin cases, 9.4 per cent. of the respiratory tract cases, and 8.8 per cent. of the cases of infectious disease were its hosts. The frequency of the association of this parasite with skin diseases in childhood suggested a causal relationship, the more so because skin tests with an ascaris extract provoked urticaria and anaphylactic phenomena. As for the frequent coincidence of infestation with this parasite and disease of the respiratory tract, the peregrinations of its larvae through the lungs may be responsible. An investigation of the story that the ascaris actively deserts its host when he or she is very ill provided little substantiation of it; and though a close watch was kept in the cases in which therapeutic pyrexia had been induced, no fugitive worm was caught during the fever. There was but one case (pneumonia in a child) in which the worm made its escape during its host's fever, and the author is inclined to suspect that, when a worm escapes from a sick host, this action is prompted by the sickness of the worm itself. The frequency and degree of eosinophilia in the hosts were lower than those of other observers, and the absence of severe anaemia was notable. It is suggested that the frequent inclusion of fish liver in the dietary of the population of East Prussia may avert an anaemia which certain intestinal parasites would otherwise provoke; and the author publishes a table showing how effective in the treatment of pernicious anaemia is a dietary of fish liver (*quappinleber*).

457

Hodgkin's Disease

A. HERZ (*Wien. Arch. klin. Med.*, 1934, vol. 24, Heft 3, p. 428) reports the results of investigation of forty-five cases of definitely established lymphogranulomatosis. There were twenty-six male and nineteen female patients, the great majority being in the third and fourth decades. Most were chronic, and in only six cases was there a rapid course leading to death in a few months. Whilst the glands first affected were generally those in the neck, the first manifestations may, he states, also occur in other regions, and the disease may remain more or less localized. The spleen was enlarged in twenty-six cases. Skin affections are described as frequent, mainly comprising unspecific affections such as pruritus, eczematous and urticarial exanthemata, etc. Herpes zoster was noted in three cases, and in a similar number there was lymphogranuloma of the skin. No characteristic blood changes could be established, though eosinophilia was sometimes marked, together with a diminution in lymphocytes. In five of the cases described foci of disease were found in the lung, but it is doubtful whether these foci could have led to symptoms during life. Herz describes specific changes in the heart as rare. In twelve cases the liver

was enlarged, and in those examined post mortem there were foci of granuloma. The intestinal tract may, he states, be the seat of extensive granulomatous infiltration and may only be recognized at operation or post mortem. In three cases granulomatous nodes were found in the bone marrow, the blood giving no indication of an irritation of this structure. No symptoms of involvement of, or pressure on, nervous tissue were found in the series. The author advocates properly controlled x-radiation over large areas.

458 Sweating as a Symptom of Heart Failure

Profuse sweating, accompanied by coldness of the extremities, pallor, and tachycardia, is regarded by J. URIOST and R. P. BLANCO (*Arch. des Mal. du Cœur*, March, 1934, p. 155) as a symptom of grave significance in certain forms of heart disease. It is thought that those disturbances of cardiac function which lead to acute pulmonary oedema or angina pectoris may alternatively express themselves on occasion by the syndrome, of which sweating is the chief symptom described, and which has been termed "diaphoretic asthose." The clinical features of the attacks lead the authors to conclude that they must be considered as equivalents of angina or acute pulmonary oedema. They appear to be provoked by exertion. They are accompanied by a low blood pressure, restlessness, and a feeling of indefinable malaise, and, finally, are relieved by depletive measures—morphine and strophanthin. As in acute pulmonary oedema and anginal pain, it is suggested that the pathological basis of the sweat crises is sometimes an infarction of the myocardium.

459 Suprarenal Insufficiency in Typhoid Fever

W. RUBINSZTEIN (*Thèse de Paris*, 1934, No. 130), who records eight illustrative cases in patients aged from 3 to 46, states that typhoid fever is one of the infectious diseases which most tend to affect the suprarenals, whose function it is to regulate the blood pressure and to act as an antitoxic defence to the system. Suprarenal involvement is manifested by a typhoid state, prostration, and a low blood pressure, such symptoms being most marked in the ataxo-adyamic, asthenic, and pseudo-meningeal forms of typhoid fever. The development of suprarenal incompetence due to the typhoid toxin explains the occurrence of certain syndromes in the course of typhoid fever, such as attacks of hypothermia and the syndrome of pseudo-perforation. Slight involvement of the suprarenals in the course of typhoid fever may be the starting-point of a slowly developing syndrome of suprarenal incompetence at a more or less distant date. The diagnosis is of the utmost importance, as the prognosis depends on the early application of treatment, which should consist in the administration of adrenaline or suprarenal extract.

Surgery

460 Radium Treatment of Cancer of the Lip

K. F. B. BUCH (*Ugeskrift for Læger*, April 5th, 1934, p. 376) reports from the Radium Station in Aarhus, Denmark, 157 cases of cancer of the lip observed from the beginning of 1923 to the end of 1932. In every case the diagnosis was confirmed by microscopical examination. The patients' ages ranged from 39 to 87 years, the average age being 62. Of the 144 patients with cancer of the lower lip, as many as 136 were men, whereas of the thirteen patients with cancer of the upper lip seven were women. In nearly all the cases the symptoms had lasted for less than a year. There were forty-five who were much addicted to tobacco, and twenty-six who suffered from severe pyorrhoea. In thirteen cases there was a history of trauma. The cases were classed as operable when the diameter of the lesion was under 2 cm., and when there was no evidence of metastases. Thus defined,

there were 113 operable and forty-four inoperable cases. After a year's observation, 101 of the operable and thirty of the inoperable were still alive. Of a total of 112 patients observed for three years, as many as ninety were symptom-free at the end of this period. A study of the deaths from cancer showed that nearly all of them occurred within the first two years after treatment. There were, of course, several deaths from intercurrent diseases, notably among the patients already over 70; and when such deaths occurred more than two years after the institution of radium treatment the case was included for statistical purposes among the cures. There were nineteen cases in which the radium treatment of the primary tumour had to be repeated, as traces of the disease persisted; all these cases became symptom-free. There were also thirty-four cases in which a relapse occurred, but it proved fatal only in twenty cases. In his study in the literature of the comparative merits of operative and radiological treatment of cancer of the lip, the author shows that the former assures recovery in 60 per cent., whereas the latter does so in 80 to 85 per cent. of the operable cases.

461 Rupture of the Bladder

L. BOGART (*Amer. Journ. Surg.*, March, 1934, p. 442) classifies bladder injuries as intraperitoneal or extraperitoneal, and traumatic or spontaneous. Trauma, external or internal, is the most common cause of the lesion, which occurs far more frequently in males than in females, owing to the more protected position of the bladder in women. Predisposing causes are full bladder and diseased bladder, with chronic distension and alcoholism. Associated injuries of the traumatic type are usually fractures of the pelvis, and are most common in extraperitoneal cases. In cases of intraperitoneal rupture the most common site is the posterior superior portion, and in extraperitoneal rupture the neck is the most frequent site. In the former variety the abdomen becomes filled with urine, which becomes infected and causes an active peritonitis. In the extraperitoneal variety the space of Retzius becomes filled with blood and urine, and appears oedematous and fluctuating. Symptoms in these cases are shock, strangury, pain above the pubis with bulging, infiltration of the deep perineum or abdominal wall and of the superficial abdominal fascia, symptoms of infection, and uraemia. In cases of intraperitoneal rupture the injury may be slight. The early symptoms are shock, severe pain in the bladder, strangury, urine or blood trickling through the urethra, peritoneal irritation, and catheterization of bloody urine or clear blood. Later symptoms are principally abdominal, with distension, pain, and peritonitis, ileus, fluid in the abdomen, and uraemia. In cases of intraperitoneal rupture laparotomy should be performed as soon as possible, with closure of the opening and suture of the serous and muscular coats. If the mucosa is sutured absorbable sutures only should be used. Operative treatment in cases of extraperitoneal rupture should consist in exposing and closing the rupture, combined with bladder drainage. Mortality depends on early diagnosis and immediate treatment. Six cases are reported, with four recoveries.

462 Joint Injuries in Pneumatic Drill Workers

According to P. ROSTECK (*Zentralbl. f. Chir.*, March 17th, 1934, p. 630) the vibration of compressed-air tools may produce in those using them morbid changes in (1) joint capsules and the adjacent points of insertion of muscles into bones, and (2) the articular cartilage and underlying bones. The former changes are due to degeneration followed by calcification; they are typically seen in the lower end of the humerus near the attachment of the capsule of the elbow-joint and the insertion of the brachialis internus. In joints such as those of the hand, in which vibration cannot be compensated by muscular activity, pressure-necroses of the articular cartilage are followed by partial necrosis of the underlying bones, with formation of free bodies and an osteochondritis dissecans. Necrosis of the semilunar is much more common than in the os magnum and scaphoid bones. Morbid changes in the

shoulder-joint (periarticular bony outgrowths below the glenoid cavity, and from the adjacent part of the head of the humerus) are much rarer than in the superior radio-ulnar joint. The frequency of pneumatic drill disease has been exaggerated: in the Ruhr coal area only some 300 cases have come to medico-legal notice.

Therapeutics

463 Treatment of Radio-dermatitis

CRAPS and A. ALECHINSKY (*Le Scalpel*, April 14th, 1934, p. 497) have found a combined treatment with silver nitrate and ultra-violet rays to be most beneficial in radio-dermatitis. A similar method has been previously employed by Schindler in chronic peribuccal or intertriginous eczema, by Huldshinsky in infantile eczema, and by Boisson in microbial dermo-epidermatitis and dermatomycoses. The present authors employed it in radio-dermatitis, owing to the results they obtained in other cutaneous affections necessitating stimulation of the cellular vitality and of cicatricial repair. The following is their technique. The healthy parts being suitably protected, the lesions are completely coated with a 5 per cent. solution of silver nitrate (Schindler uses an alcoholic solution); this is applied without rough friction after removal of scales and crusts; to facilitate its adherence and absorption, the lesion may be previously cleansed with sulphuric ether. The affected area is then irradiated by a mercury-vapour quartz lamp at as close a distance as possible, dependent on the extent of the field to be treated and the heat given by the lamp. The optimum distance for a Bach lamp with large reflector is 20 cm., for a Dufestel or Kromayer one 10 cm. The duration of irradiation is five to ten minutes; it must cause complete drying of the solution and blackening of the treated area. Should the blackening be insufficient, silver nitrate is again applied. Drying of the lesion usually occurs at the first application; the treated region is then merely covered with a sterile gauze compress. No fatty substances should be applied during treatment. Irradiations are made every two days. The pain of the dermatitis often disappears after one or two applications, and cicatrization commences rapidly and progresses regularly. No failures have occurred with this method. Notes of five cases are appended.

464 Cod-liver Oil Applied to Wounds

W. LÖHR (*Deut. med. Woch.*, April 13th, 1934, p. 561) has during the past three years treated several thousands of cases with cod-liver oil applied as a local dressing to wounds. He was prompted to do so by the successes achieved with cod-liver oil in children whose convalescence from infections had hitherto been protracted. In the treatment of wounds, chemical disinfectants should be used as much as possible, as well as foreign bodies removed as drains and strips of gauze. It is not clear how cod-liver oil acts locally; but it is, like most other oils, practically sterile, and when staphylococci, streptococci, and other germs are introduced into it, they are soon destroyed. As cod-liver oil is too fluid by itself, it is combined with other fatty substances in an ointment which is fairly firm at room temperature. This ointment is pasted in a thick layer over a wound, the discharge from which oozes out from under it. It tends to saturate the tissues with which it comes in contact and to promote the separation of living from dead tissues. This treatment is not indicated in acute inflammatory processes, but it is useful in recent wounds, when there is little or no infection, and also in chronic, sluggish conditions, such as varicose ulcers. Once the tissues have shown themselves capable of some degree of resistance to an infection, the additional stimulus given by cod-liver oil proves most useful. Burns and bed-sores also react satisfactorily to the treatment, which possesses the great advantage of being quite painless. In burns, the amount of cod-liver oil required is considerable, but this expense is more than repaid by the increased rate of recovery. While the author admits that the vitamins in cod-liver oil may be

more or less responsible for its local therapeutic properties, he is inclined at the present stage to observe facts rather than to try to interpret them.

465 Urinary Antiseptics in Relation to Fluid Intake

N. F. MILLER and C. C. CHU (*Amer. Journ. Surg.*, March, 1934, p. 557) have conducted an investigation to determine the relative effectiveness of urinary antiseptics to the amount of the fluid intake. They administered standard doses of urinary antiseptics to laboratory animals, first on limited fluids and later on forced fluids, with simultaneous bacteriological studies to estimate the efficiency and inhibitory influence of the excreted drug. They also administered urinary antiseptics to a group of voluntarily co-operative patients, at first on restricted fluids and later on a high fluid intake, with bacteriological tests to ascertain the power of the excreted antiseptic to inhibit bacterial growth in the urine. Evidence was obtained that the restriction of fluids during the time of administering antiseptic drugs definitely enhanced the inhibitory power of the drug on bacterial growth in the urine. The patient's immediate needs have to be considered, however, in applying the conclusions. For example, patients with urinary tract infection and high pyrexia are probably better treated with a high fluid intake until the time when the febrile reaction has subsided. Since the inhibition of bacterial growth noted in rabbits and human subjects receiving urotropine was considerable, the question arose whether this inhibition was referable to the urotropine or to the ammonium chloride which was being given concurrently. The exhibition of ammonium chloride alone was found to have no notable inhibitory effect, thus revealing that the action was attributable to the urotropine.

Laryngology and Otology

466

Tracheotomy

F. A. FIGI (*Proc. Staff Meetings Mayo Clinic*, February 7th, 1934, p. 86) reviews a series of 205 tracheotomies performed on 200 patients, seventy-one being emergencies and 135 elective. The most frequently encountered primary pathological conditions necessitating tracheotomy were: carcinoma of the larynx (133 cases), goitre (twenty-five cases), foreign bodies in the tracheo-bronchial tree (fourteen cases), and multiple papilloma of the larynx (eight cases). Although there was no immediate surgical mortality directly attributable to the operation, eighteen patients died subsequently. Bronchopneumonia was the most common post-operative complication, but it occurred in only thirteen cases in the entire series, and was probably already present in two of these before the trachea was opened. Only three of these thirteen patients recovered. Mediastinitis was not encountered in a single instance. The deaths in the series were almost entirely the result of dyspnoea and delay in opening the trachea rather than of the tracheotomy.

467 Sclerosing Injections in Hypertrophic Rhinitis

Alluding to the rich nasal vascular supply and to the frequent ill effects (slow cicatrization of the scar, escessive necrosis, etc.) following galvano- or thermo-cauterization, W. J. BONTINEK (*Rev. de Laryngol., d'Otol. et de Rhinol.*, December, 1933, p. 1285) discusses the use of sclerosing injections in hypertrophic rhinitis while the condition is still in the congestive retractile state. Though the ultimate effects of this treatment have yet to be ascertained, the immediate results have, he states, been so successful as to lead to its possible employment in other conditions. The substances used are a 5 per cent. solution of the double hydrochlorate of quinine and urea, an 80 per cent. solution of glycerin, "sclero-serum," and glucose solution. As the injection of sclero-serum is more painful and glucose gives less encouraging results, the two former are chiefly employed. Bontinek prefers glycerin. This substance occasions a mild but rapid and complete phlebo-sclerosis (due to its concentration), is perfectly tolerated, and its injection is painless. At least

10 c.cm. is injected into the diseased turbinates at two different times. Local cocaine-adrenaline anaesthesia of ten minutes' duration is performed to ensure perfect retraction. A Luer or Robert's syringe is used with eccentric end and a needle of 8 cm. length and 8/10 mm. calibre, having a short bevel. The needle is forced into the turbinate with its head towards the back and just grazing the bone; the injection is made while withdrawing it; if an osseous irregularity is present, two or three injections are made. Dutheillett advises a further injection at the inferior face of the turbinate. Immediately after the injection a sufficiently tight tampon is inserted to prevent haemorrhage and reflux of the liquid. Three to five days later a second exactly similar injection is made. No complications ensue after this operation. The only change noted for a few days is a slight hydropnoea. Improvement commences in from fifteen to twenty-one days.

468 Punctured Wounds of the Oesophagus

A. J. WRIGHT (*Journ. Laryngol. and Otol.*, March, 1934, p. 175) records three cases of accidental puncture of the oesophageal wall by bone fragments, with serious complications resulting from neglect or unwise intervention. He concludes that any history of the supposed sticking of a small fragment of bone in the throat should always be regarded with respect. The blind passage of instruments in such a case should be strictly avoided as being likely to force the foreign body more deeply into the tissues. The persistence of pain on swallowing, or its increase after the lapse of a period of twenty-four hours or so, makes the presence of a foreign body highly probable. Local tenderness on pressure over the trachea is a sign of considerable importance in such a case. Where the presence of a sharp fragment of bone is likely, oesophagostomy should be performed at the earliest possible moment and in spite of a negative x-ray examination. A small splinter of bone cannot as a rule be identified in a radiogram. In spite of early removal infective complications may follow a punctured wound of the oesophagus, but such complications are not invariably fatal. Gastrostomy would seem to be indicated immediately if there is any sign of the passage of food through the perforation in the oesophageal wall. Wright considers that there is probably a greater capacity for the localization of infection in the loose peri-oesophageal tissues than is generally supposed.

469

Treatment of Cancer of the Larynx

K. AMERSBACH and L. KRAUS (*Med. Klinik*, March 9th, 1934, p. 321) report from Prague their experiences with the treatment of cancer of the larynx and hypopharynx between October, 1927, and December, 1933. Their material in this period consisted of 163 cases, fifty-six of which concerned the hypopharynx and the remainder the larynx. For more than twenty years Professor Amersbach has familiarized himself with the operative, Roentgen, and radium treatment of laryngeal cancer, and the present paper represents the balancing of his experiences and opinions. With the introduction of Coutard's x-ray technique it would now seem that, where cancer of the hypopharynx is concerned, this system is at present the best. When the disease is extensive, and either the radiologist or the patient refuses x-ray treatment, "intratumoral" radium treatment is indicated, as it usually rids the patient of dysphagia and renders life less unbearable. Indeed, it lengthens the expectation of life in such desperate cases for from six to sixteen months. Though Coutard's technique has contributed greatly to the displacement of operative treatment in favour of the x rays, it must be remembered that this procedure demands much of the patient's general vitality, and also provokes a very troublesome irritation of the skin and mucous membranes. However, the call made on the organism by an operation is even more exhausting, and if the authors still prefer operative treatment when the disease is limited to the vocal cords and epiglottitis it is because they lack experience of the late results of Coutard's treatment.

Obstetrics and Gynaecology

470 Surgical Treatment of Dysmenorrhoea

J. L. DE COURCY (*Amer. Journ. Surg.*, March, 1934, p. 408) strongly recommends resection of the presacral nerve for the relief of obstinate cases of dysmenorrhoea which have proved resistant to ordinary measures. In six months he has obtained immediate favourable results in a series of twenty-one cases, but his final statistics await the test of time. He agrees with Cotte that the indications for this operation are pelvic neuralgia, vaginismus, resistant dysmenorrhoea, uterine hypoplasia accompanied by insufficient and painful menstruation, metrorrhagia of ovarian origin, and certain sexual neuroses such as nymphomania. In women, section of the presacral nerve does not lead to any loss of vesical control. In his technique De Courcy places the woman in the Trendelenburg position, opens the abdomen through a left rectus incision, deals with any pathological condition of the ovaries and uterus, removes the appendix as a routine, opens the posterior parietal peritoneum, and strips away the nerve fibres in the triangle between the right iliac artery and the left pelvic vein. Pain is immediately relieved, and menstruation regularly ensues within forty-eight to seventy-two hours later, no matter at what stage of the menstrual cycle the operation has been performed. Most of the author's patients had to be catheterized for two or three days subsequently, but the inhibition of bladder function was no more marked than in the case of any other gynaecological operation. Several patients later became pregnant. De Courcy remarks that the technique is somewhat delicate, requiring a discriminating eye. Given the right conditions it affords a means of aiding a large class of women who must otherwise suffer a monthly martyrdom, as well as a chronic disability involving lowered physical and mental efficiency.

471 Vitamin Enrichment of Human Milk

With a view to increasing the concentration of vitamin A in breast milk, SYLVIA S. McCOSH *et al.* (*Journ. of Nutrition*, March 10th, 1934, p. 331) administered daily doses of 15 grams of cod-liver oil in gelatin capsules to three lactating women. Six weeks after parturition, when the mature milk flow had been established, samples were repeatedly taken to determine the average vitamin A content in each. Cod-liver oil administration was then begun. The quantity of milk secreted daily by each woman remained approximately unaltered throughout the investigation, as did the fat content. The results of the biological assays were based upon the average gain in body weight of experimental rats and on vaginal smear records. It was found that no increased content in the milk of vitamin A could be detected. The authors conclude that there appears to be no way of transferring increased quantities of vitamin to maternal milk when women are on an adequate diet, but that starvation may well be capable of being relieved by such adjuvant measures. Reference is made to the literature to show that this inability of augmentation appears to hold also for vitamin B, but not for vitamin G, which is increased by supplementing the diet with daily doses of 10 grams of yeast.

472 Utero-vaginal Prolapse as a Cause of Uraemia

A. BELLO (*Semana Médica*, March 15th, 1934, p. 819), impressed by the similarity between prostatic enlargement in its first and second stages and prolapse of the uterus and vagina (in that both conditions produce deformity and dilatation of the ureters), has been investigating the incidence of nephritic phenomena in females with prolapsed uterus and cystocele. He notes that the insertion of the ureter into the bladder changes its relations *passu* with the degree of prolapse, so that the intra-parietal and terminal portions of both ureters become stretched and flattened, so reducing the ureteral calibre until it becomes almost entirely obliterated. To this is

added traction on the uterine blood vessels, and the combination of both phenomena produces dilatation of the ureters above the site of the compression with resulting damage to the renal pelvis and, later, uraemia. In such patients he has frequently observed a high blood urea, quite irrespective of their age, but this becomes markedly reduced, or may altogether disappear, when the prolapse has been successfully cured by operation, except when the damage to the renal pelvis is irretrievable. Further, he notes that, even if the blood urea be not substantially diminished after operation, the general condition of such patients is almost constantly improved, both mentally and physically. He deprecates the idea, so often expressed, that the aged should not be operated upon for the relief of their prolapse, and states that, apart from advanced cardiac and renal changes, old age offers no contraindication to hysterectomy combined with perineal repair. Details of operative treatment are not given.

Pathology

473 The Pathogenicity of *B. alkalescens*

H. WELCH and F. L. MICKLE (*Amer. Journ. Pub. Health*, March, 1934, p. 219) have isolated an organism similar to that described by Andrewes as *B. alkalescens* from an outbreak of what seems to have resembled food poisoning in some respects and dysentery in others. The outbreak, in which several students and two nurses developed abdominal pain and diarrhoea, occurred in a university infirmary. *B. alkalescens* was isolated from the faeces of each of the patients and from those of a healthy person employed in handling the food. Agglutinins acting on the organism were demonstrable in the blood serum of the patients after some time. The healthy carrier was removed, and no further cases occurred. *B. alkalescens* was also isolated from the urine of four patients with chronic nephritis. Agglutination and absorption studies seemed to show that the strains of *alkalescens* were closely related to each other antigenically, and had some relation to other members of the dysentery group. All strains were non-motile. Acid was produced in glucose, maltose, and mannite, but not in lactose or sucrose. Litmus milk was unaltered or rendered alkaline. The methyl-red test was positive, the Voges-Proskauer negative. The indole test was uniformly positive; and nitrates were reduced. The authors conclude that *B. alkalescens* must be included in the dysentery group as potentially pathogenic for man.

474 Second Attacks of Poliomyelitis

T. B. QUIGLEY (*Journ. Amer. Med. Assoc.*, March 10th, 1934, p. 752) records the case of a second attack of poliomyelitis which proved fatal. A girl aged 7 had her first attack in the course of an epidemic in August, 1931, recovered, and had no illness until mild pertussis in June, 1933, which was followed rather more than a month later by the onset of a second typical attack. A mild indefinite infection of the upper respiratory tract was followed a fortnight later by a slight sore throat and difficulty in speaking. Four days subsequently there ensued vomiting, cyanosis, and dyspnoea, which increased and caused death. The necropsy revealed changes similar to those found in the post-mortem examinations made during the previous epidemic. There was a mild haemorrhagic gastritis, with definite hyperplasia and congestion of the lymphoid tissue. The cut surface of the liver showed the characteristic pale, muddy, and granular appearance, without any specific microscopical signs. Although there was no involvement of the extremities in the second attack, yet at every level of the spinal cord which was examined there appeared marked nerve-cell degeneration, neuronophagia, congestion, and oedema. The author refers to the literature of the fourteen reported cases of true second attacks, and comments on the diagnostic criteria of this rare occurrence.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

475

Aetiology of Appendicitis

K. WESTPHAL (*Deut. med. Woch.*, April 6th and 20th, 1934, pp. 499 and 600) remarks that even in the most severe forms of appendicitis no organisms have yet been found which are not more or less frequently demonstrable in the normal appendix. Also it is the autogenous, enterogenous infection which plays the most important part in the genesis of appendicitis. Probably appendicitis does not depend on any one specific organism, but on the lowered resistance of the mucous lining of the appendix to whatever pathogenic germ may be in contact with it. Such lowered resistance may be due to more or less complete obstruction of the lumen of the appendix, microbic activity being promoted under the same conditions which favour infection of the urinary and biliary tracts when their normal evacuation is interfered with. During the past five years Professor Westphal has been studying the movements of the appendix, and in two cases of appendicular colic he has noted the changes in the shape and position of the appendix with the help of the x rays after a barium enema. Spontaneous pain and tenderness on pressure coincided with severe spastic contraction of the appendix, either in part of it or in its entirety. These observations afford an explanation of those cases in which, though the clinical picture of appendicitis was well defined, a laparotomy revealed nothing amiss with the appendix. Aschoff has observed this state of affairs in 18 per cent. of his appendicectomies. Considered from this spastic angle, a goodly proportion of cases of appendicitis should react satisfactorily to atropine, papaverine, adrenaline, etc., and when there are no immediate facilities for operation this procedure is to be recommended. The author does not, however, advocate it as a substitute for the comparatively safe operation of appendicectomy performed under ideal conditions.

476

Gastric and Colonic Flatulence

O. LLOYD-JONES and E. M. LUGEDAHN (*Med. Record*, April 4th, 1934, p. 320) discuss the mode of production and of dispersion of gas in the stomach and bowel. In addition to gas being a natural and inevitable by-product of the hydrolytic, fermentative, and oxidative processes of digestion, air is swallowed, and gases are absorbed into the alimentary canal from the blood stream. Yet in many persons there is no belching or flatus, and the gas must therefore be absorbed by the blood stream. Patients complaining of excessive gas usually present few clinical signs, and the authors have therefore started to examine them radiographically. It was found that with appropriate technique gas bubbles in the colon and large intestine were clearly demonstrable, but only rarely in the small intestine. These manifestations bore no definite relation to the extent of the symptoms, and the authors doubt whether "gas pains" exist as such; they are more probably attributable to sudden changes in the vascularity of the bowel wall or to increased gas secretion into its interior. Both eructations and the passage of flatus can be resisted voluntarily without any adverse sequelae, the gas being reabsorbed by the body. The majority of sensations referred by patients to bloating, gas, or abdominal distension come about through the same mechanism which produces gurgling, borborygmi, and excessive flatus—namely, unsynchronized contraction and dilatation of random segments of the colon, as a result of disturbed tone and irritability of the musculo-neural tissues of the bowel wall. It is therefore useless to confine therapy to measures directed towards the reduction of the production of gas. It will be necessary to soothe, rest, relax, and even depress the alimentary neuro-muscular tissue by regulating the diet and supply-

ing suitable medication. In this way the peristaltic unrest can be corrected and the synchronized rhythm restored. The authors add that patients must be taught that frequent belching is an artificially acquired habit, that even necessary belching can be conducted with no spastic or sound phenomena, and that the retention of flatus is not harmful.

477

Aural Complications of Diabetes

P. VAN DEN BOSCHE (*Thèse de Paris*, 1934, No. 203), who records forty illustrative cases in patients aged from 35 to 69, fourteen of which are original, states that aural complications are not uncommon in diabetes. Pruritus, eczema, epidermal plugs, and especially recurrent boils are the commonest lesions. Some severe forms of otitis externa may give rise to coma. As regards the middle ear, a distinction must be made between cases of severe diabetes in which necrotic mastoiditis may be observed and mild cases in which all forms of otitis may occur. There is, however, a frequent tendency to haemorrhage and a rapid extension of the process attacking the bone, which explains the relatively early occurrence of endocranial complications, the frequent delay in cicatrization, and the possibility of recurrent sequestra. As regards the internal ear, in addition to labyrinthitis secondary to suppurative otitis media, diabetes may be responsible for a number of disturbances, either indirectly, through vascular changes such as labyrinthine haemorrhages and hypertension, or directly, from alteration in the composition of the endolabyrinthine fluid, involvement of the organ of Corti, or neuritis of the auditory nerve.

478

Indoxyluria and Indoxylaemia

According to G. LAROCHE and A. GRIGAUT (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, April 13th, 1934, p. 247), an estimation of the concentration of the urinary indoxyl is a valuable test of intestinal functioning and of toxic resorption. The normal urinary indoxyl content of 10 mg. per litre may be increased to 100 mg. or more in disorders of this nature. For these estimations the authors use the morning urine and a method based on Jolles's reaction. Numerous factors influence resorption of the intestinal indole with consequent hyperindoxyluria. These, which are briefly discussed, are: water absorption and diuresis; digestive troubles; the albuminous secretions of the caecocolon; the state of the intestinal organisms and of the food; hydration of the colic contents; and, chiefly, the permeability of the caeco-colic mucosa. Thus, this test is a useful control in the treatment of intestinal disorders. The same authors (*ibid.*, p. 258) show that estimations of the blood indoxyl are of great diagnostic and prognostic value in chronic nephritis. For these tests, Grigaut's technique and Jolles's reaction are employed. Normal blood gives a negative reaction; a permanently positive reaction during chronic nephritis indicates the existence of serious lesions of the renal parenchyma; readings of 10 mg. or higher per 1,000 are evidence of a grave chronic nephritis in its final period, and death may be predicted in a few weeks or a few months. Two cases are cited to illustrate the diagnostic value of this test.

479

Cancer in Cavities of the Lung

R. GOMES DE MATOS (*Thèse de Paris*, 1934, No. 81) who records fourteen cases in patients aged from 18 to 68 states that cavities are found in a quarter of all cases of cancer of the lung. The cavities are of two kinds—namely, a frequent form, which occurs in the body of the tumour, and a rare form, which develops in its neighbourhood. Both forms may be either necrotic or suppurative. Necrotic cavities, whether occurring in or by the side of the tumour, are accompanied by few clinical or radiological signs, and have little effect on the general condition, but they may give rise to haemoptysis.

Suppurative cavities, on the other hand, are almost always situated in the new growth. They have a considerable effect on the general condition, for, besides causing haemoptysis, they are always accompanied by profuse purulent expectoration, and are usually manifested by clinical and radiological signs. The initial lesion is necrosis, which results from circulatory changes in the bronchial vessels obliterated or compressed in cavities. Infection is always a secondary phenomenon.

Surgery

480 Elective Indications for Sympathetic Resection

W. RIÉDER (*Zentralbl. f. Chir.*, March 31st, 1934, p. 734) concedes that in morbid vasomotor conditions of the limbs (Raynaud's disease, causalgia, endarteritis obliterans, etc.) the effect of surgical excision of the sympathetic cord or its contributory rami, although frequently excellent, may be disappointing. He finds that a preoperative prognosis may be made by measuring the rise in cutaneous temperature which occurs in the limb concerned after induction of spinal or plexus anaesthesia. A rise in temperature of less than 1° C. indicates that operation will be of little benefit, but if a satisfactory local pyrexia is noted the operation can be carried on forthwith. Six illustrative cases are described. Rieder finds that after peripheral periarterial sympathectomy the rise of skin temperature is temporary, but that after the more central operation it is lasting.

481 Treatment of Congenital Pyloric Stenosis

A. ECKSTEIN (*Klin. Woch.*, February 24th, 1934, p. 295), who describes 202 cases of this condition, of which ninety-two were treated by medical and 110 by surgical methods, finds that the latter were undoubtedly superior to the former. Under identical conditions and a uniform distribution of subjects the mortality of the medical cases amounted to 18.4 per cent., while that of the surgical cases did not exceed 3.4 per cent. Needless to say, such results are only obtained through complete mastery of surgical technique and careful post-operative treatment. The average duration of treatment was ninety-one days for medical and only thirty-four days for surgical cases.

482 Actinomycosis

A. GRAVES and A. OCHSNER (*Amer. Journ. Surg.*, January, 1934, p. 54) state that the organisms causing actinomycosis are widespread and occur in dust, pollen, or in the chaff from grain stalks. The saprophytic members of the group are found also in the soil, in the alimentary tracts of insects, in the tonsillar crypts, and in the gastro-intestinal tract in man. It is most common in the third and fourth decades of life, and 80 per cent. of cases occur in males. In a series of 680 cases it was found that 60 per cent. of lesions occurred in the head and neck, 14 per cent. in the thorax and lungs, 18 per cent. in the abdomen, and the remaining 8 per cent. as generalized infections in various parts of the body. In the abdominal type of actinomycosis the symptoms may be chronic, when a palpable mass is the first sign of the disease, or acute, when the symptoms of acute appendicitis are present and appendicectomy is usually performed. During convalescence an abscess forms, the incision of which is followed by the formation of a persistent sinus. If the disease is not eradicated while it is still localized, multiple abscesses will form, and treatment will be impossible. The common route of spread is by continuity following the growth of the fungus along fascia and muscle. Ultimately the blood stream may become infected and cause metastatic lesions. Two cases are reported where the actinomycosis spread from the caecum to the subphrenic space, causing a subphrenic abscess some weeks after an appendicectomy had been carried out. Both cases ended fatally after drainage and partial excision of the infected tissue. It is suggested that early recognition of the

disease will increase the hope of successful operation. Drainage of a subphrenic abscess by a retroperitone approach is of great advantage when the abscess is due to actinomycosis. In all cases large doses of potassium or sodium iodide should be given post-operatively, and intensive deep x rays should be used.

Therapeutics

483 Intravenous Serum Therapy in Gonococcal Arthritis

L. MATEOS (*Rev. Med. de Barcelona*, March, 1934, p. 27) declares that this is the treatment of election on account of its speedy action and efficacy. It is not followed by early "serum accidents," and its curative effects are constant. None the less he notes that the later complications of serum injection often follow, even though the disappear quickly when treated by calcium chloride, magnesium hyposulphite, and adrenalin. The biological and morphological affinity of the meningococcus and gonococcus induced Heresco and Calic to employ antimeningococcal serum in four cases of gonococcal arthritis with results so successful that Colic and Weaver followed the example, but employed it intravenously. Mateos treated ten cases with antigonococcal serum, and his results have convinced him of its superexcellence. The method which he used is as follows. Antigonococcal serum (20 c.cm. in 200 c.cm. of slightly hypertonic saline—9 per 1,000) is slowly injected into a vein of the fasting patient. Forty eight hours later 30 c.cm. in 300 c.cm. of saline is similarly given, and followed at like intervals with 40 c.cm. of serum in 400 c.cm. saline, and finally, 50 c.cm. serum in 500 c.cm. of saline. By the time that the last injection has been given all pain and exudation will have disappeared, and a little massage and diathermy will complete the cure.

484 Endocrine Therapy in Arthritis

In the course of research on the cerebro-spinal fluid F. NEGRO (*Med. Welt*, April 7th, 1934, p. 480) found a striking improvement in a case of primary ankylosing polyarthritis on administering parenterally great doses of cerebro-spinal fluid from the horse. Convinced that this result was due to the hormone content (particularly the posterior pituitary) of the cerebro-spinal fluid, the author treated twenty-six cases of ankylosing polyarthritis with posterior pituitary extract in large doses. Seven of these cases are described in detail. Five showed marked improvement, while two were complete failures. Of the remaining nineteen cases eighteen were successful and only one failed to improve. Negro concludes that certain diseases of the joints are probably due to an insufficiency of the pituitary gland, and that certain cases of chronic primary ankylosing polyarthritis may be favourably influenced by the administration of posterior pituitary hormones.

485 Treatment of Pulmonary Tuberculosis in Diabetics

According to M. LABBÉ, R. BOULIN, JUSTIN-BESANÇON, and J. E. THIÉRY (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, February 9th, 1934, p. 204) artificial pneumothorax, completed if necessary by phrenic avulsion and combined with insulin therapy, is the only hopeful line of treatment in diabetics having pulmonary tuberculosis. Unfortunately, effective collapse is difficult to induce in these patients, whose lesions are apt to be diffuse, bilateral, and rapidly progressive, and in whom inflation is particularly liable (46 per cent.) to be followed by effusion. Young subjects, in spite of wasting, respond better than the aged, and men better than women. Of a series of twenty-six cases ten survived, two having a pneumothorax of some two years' duration, and seven having had effusions followed by adhesion (two to five years). The sixteen lethal cases included four in which artificial pneumothorax could not be induced on the contralateral

side because of adhesions, one of speedy pleuro-pulmonary perforation, and one in which a sero-fibrinous-exudate became purulent: nevertheless the time of survival reached in some cases two to four years, and was considerably greater on the average than that of diabetes otherwise treated—namely, two to eighteen months.

Anaesthetics

486 Intravenous Sodium Soneryl as a Basal Anaesthetic

B. DESPLAS and Mlle G. CHEVILLON (*Bull. et Mém. Soc. Nat. de Chir.*, March 31st, 1934, p. 519) state that sodium soneryl possesses the greatest coefficients of security and utilization of all the barbituric derivatives, and may be used for long operations without the danger of overdosage. It has a profound narcotic action, causing lowering of the arterial tension and diminution of the respiratory amplitude. The latter can be prevented by a few whiffs of carbon dioxide at the commencement of the anaesthesia, and the fall in blood pressure, if necessary, by the same means, together with injections of ephedrine. The drug has no effect on the hepato-renal elimination. The authors use the following technique. The evening before operation 0.3 grain of soneryl is given orally; this calms the patient and ensures a good night's sleep. Half an hour before the anaesthesia an intravenous injection of a 5 per cent. aqueous solution of the drug is given in doses of 1 cg. per kilo of weight. The injection must be given very slowly, and strict attention paid to the pulse, respiration, and arterial tension. This may be followed by a general anaesthesia with ether, regional anaesthesia, or no other anaesthetic may be required. Regional anaesthesia permits of all interventions above the abdomen; the spinal method should be reserved for subumbilical operations and those on the lower extremities. Soneryl associated with ether is the anaesthetic of choice for operations on the stomach and the biliary passages. The authors report that no failure occurred in eighty-seven anaesthesias with intravenous soneryl; the anaesthesia was always sufficient, and no post-operative complications or deaths attributable to the anaesthetic occurred.

487 Short Anaesthesia with Evipan

J. NORDENTORP (*Hospitaltidende*, February 27th, 1934, p. 281) reports from a Danish hospital his experiences of intravenous injections of sodium evipan. This barbituric acid preparation decomposes rapidly in the body, so that the general anaesthesia it induces is very brief and practically free from danger. The cases for which it is primarily recommended are those in which ethyl chloride or a short ether anaesthesia has hitherto been employed. The dry contents of an ampoule (1 gram of powder) are dissolved in 10 c.cm. of water. Four c.cm. of the solution is injected into a vein of the arm in the course of one minute, and 6 c.cm. in the second minute at the rate of 1 c.cm. every ten seconds. The anaesthesia is complete at the end of the second minute, but if the operation is very short the operator may wait two or three minutes so as to assure a still more complete narcosis. At the author's hospital evipan has been given between March and November, 1933, to fifty-five patients for whom, with only one exception, it was not necessary to give any supplementary anaesthetic. There were no alarming incidents. The age of the youngest patient was 9 years, that of the oldest patient 86 years. In forty-three of the fifty-five cases the anaesthesia proved satisfactory. Among the twelve cases in which the evipan did not give full satisfaction were four cuttings of the uterus. None of the four appendicectomies lasted over fifteen minutes, and in only one of these cases was it necessary to supplement with ethyl chloride. The average interval in forty-five cases between the injection of the anaesthetic and the patient's response to questions was thirty-eight minutes. The author concludes that for operations not lasting more than fifteen to twenty minutes evipan is

a useful general anaesthetic which, if its action is not prolonged enough, can be supplemented by another anaesthetic such as ether.

488 Spinal Anaesthesia with Percaine

VAN ERPS (*Journ. de Chir. et Ann. Soc. Belge de Chir.*, February, 1934, p. 90) gives a short summary of 125 spinal anaesthesias with weak solutions (1 in 1,500) of percaine given by Jones's technique. This method was not employed in certain cases, such as cachectics, the aged, etc. All preoperative care was taken, but no narcotics were given, as the author believes that these, especially scopolamine-morphine, are contraindicated in spinal anaesthesia. If agitation, nausea, or vomiting occurred at the commencement of or during the operation a few whiffs of carbogene were given. A condensed table shows that twenty-two patients suffered post-anaesthetic effects—headaches, nausea, and vomiting. The headaches started from the second to the twelfth day, were frequently accompanied by fever, and disappeared in two hours after a daily injection of septicemine, which proved the only satisfactory remedy. Nausea and vomiting, he states, caused by tensional variations in the cerebro-spinal fluid; ephedrinized patients presenting these symptoms together with agitation rarely showed respiratory signs. These after-effects were relieved by carbogene, which stimulates the respiratory centre, increases the tone of the inspiratory muscles, and is antispasmodic to the arterioles in general. Serious sequelae, such as paraplegia or paralysis of the sixth pair of nerves, were not noted, but only a transient paresis or vesical paralysis. Van Erps maintains that these post-anaesthetic manifestations should not prevent the use of this anaesthesia in view of the operative facility and abdominal relaxation obtained by it.

489 Choice of Anaesthetic in Diabetes, Pulmonary Disease, and Children

In diabetic patients requiring some surgical operation B. C. SMITH (*New York State Journ. Med.*, March 1st, 1934, p. 175) does not use ether because it provokes or exacerbates acidosis. He frequently employs spinal anaesthesia in abdominal work, but only occasionally in amputations, when pulmonary complications contraindicate a short nitrous-oxide-oxygen administration. Ethylene is disliked owing to its risk of explosion. Infiltration with novocain is commended in non-inflammatory lesions, and the author has used it occasionally for leg amputations in cases with acute pulmonary complications. Avertin is not suitable owing to its depressing effect on the blood pressure. Smith considers nitrous oxide and oxygen the best anaesthetic for amputation of the toes, legs, and thighs; incisions and drainage of infected parts; breast operations; plastic procedures; and as a supplementary to spinal anaesthesia. In abdominal operations he introduces novocain in spinal fluid at a point between the third and fourth lumbar vertebrae, preceding it with an intramuscular injection of ephedrine. In operations on patients with chronic pulmonary disease F. B. BERRY (*ibid.*, p. 183) prefers *nembutal* as the basal anaesthetic to avertin and amyral, which are respiratory depressants with prolonged action. He gives 90 grains of sodium bromide on the night before the operation; this is followed by 3 grains of luminal or 1½ grains of *nembutal* one and a half hours before the operation, and 1/6 grain of morphine with 1/200 grain of hyoscine one hour later. For the general anaesthetic ethylene is preferred to nitrous oxide, because it affords better relaxation and an abundance of oxygen. In acute pulmonary cases Berry uses spinal, regional, or local anaesthesia whenever possible, and he has recently been employing high spinal anaesthesia for some upper stage thoracoplasties with good results, though he thinks that there may be an unjustifiably thin line of reserve and safety in operations above the level of the mid-thoracic region. In this group rectal ether, inhalation anaesthesia, ethylene, or nitrous oxide, preceded by adequate basal preparation, can be used with perfect safety. E. J. DONOVAN (*ibid.*, p. 187) insists

that the open cone ether method is essential for operations on children. He has found it advisable to induce anaesthesia with ethyl chloride, and to follow by the open drop ether method. The only indication for local or spinal anaesthesia is the presence of an acute respiratory infection. Avertin as a basal anaesthetic is better tolerated by children than by adults.

Obstetrics and Gynaecology

490 The So-called "Safe Periods"

The existence of periods of sterility during the menstrual cycle in women of child-bearing age is confidently asserted by A. C. NUÑEZ (*Crónica Médica*, March 15th, 1934, p. 176), although he acknowledges that the moralists Capellmann, Ferreres, and Lehmkuhl, none of whom was a physiologist, were wrong in their estimation of the times at which these periods occur. Basing his calculations on the assumption that the ovule survives its liberation and deposition for no more than two days, and that the spermatozoon lives free in the female genital tract for but four, Nuñez concludes that coitus (1) antecedent to the four days prior to the deposition of the ovule, and (2) after the second day subsequent thereto, must of necessity be infertile. Hence it follows that, for women whose menstrual cycle is of regular twenty-eight-day type, calculation of the "safe periods" is easy. For those whose cycles occur with regularity at definite periods, but of a duration longer or shorter than twenty-eight days, he has drawn up a table or "ready reckoner" which he alleges is of great value. Nevertheless, he admits that since dehiscence of the follicle does not occur with mathematical precision, inasmuch as its maturation and rupture may be precipitated by causes which he mentions, and as a second follicle may rupture prematurely, errors of calculation are possible, though unlikely. And though not a little dubious of the theory that the sperm lives but four days in its feminine surroundings, he adduces the cases of eighty-seven women of eight different nationalities who were partners in 725 complete acts of coitus during the periods mentioned, none of which were fecund.

491 Haemorrhage at the Menopause

J. QUÉNU and C. BÉCLÈRE (*Bull. Soc. d'Obstét. et de Gynéc. de Paris*, November, 1933; p. 742) analyse forty-four cases of menopausal metrorrhagia. While 27 per cent. are due to organic causes, such as carcinoma of the fundus uteri (9 per cent.), fibroma, polyp, etc., they regard no less than 73 per cent. as functional—of ovarian origin, either hormonal or infective. For this group they suggest the term "benign glandular hyperplasia." For all cases of menorrhagia at the menopause, they strongly advocate diagnostic curettage. Of the benign cases, two-thirds are cured by curettage without further treatment. The remaining one-third start bleeding again after a few months, and for these x-ray treatment of the ovaries is recommended to hasten the menopause. In a subsequent paper C. Bécère further discusses benign glandular hyperplasia. Analysing thirty-eight more cases of menopausal metrorrhagia, he attributes 64 per cent. to this condition. Microscopically, these cases show no inflammatory or neoplastic change, the uterine mucosa having the physiological appearances of premenstruation and nidation. That these are due to a modification of the ovarian hormones is borne out by the fact that if these cases are treated by x rays to ovaries only, the haemorrhage is arrested, whereas after curettage it often recurs and continues till ovarian function finally ceases at the menopause. The clinical syndrome is: (1) abrupt onset of metrorrhagia in patients previously regular in menstruation; (2) periods of two to three months' complete amenorrhoea; (3) irregular alternation of amenorrhoea and metrorrhagia. These features, in the author's opinion, further indicate the origin of the bleeding to be ovarian

dysfunction, since in cases of pathological changes in the uterine mucosa there is usually some previous menstrual irregularity and no such periods of amenorrhoea. Although the syndrome described is characteristic of functional metrorrhagia of ovarian origin, curettage and microscopic examination of the debris is recommended, both to confirm diagnosis and to stop haemorrhage temporarily at least pending permanent cure by the application of x rays to the ovaries. In atypical cases hystero-graphy should precede curettage to indicate any area of the uterus particularly suspicious of pathological change.

Pathology

492 Detection and Estimation of α -Dinitrophenol

The phenol derivative α -dinitrophenol greatly stimulates metabolism, and is being applied on an increasing scale to the treatment of obesity. A. BOLLIGER (*Med. Journ. of Australia*, March 17th, 1934, p. 367) points out that its success in this respect may lead to the appearance of proprietary products containing it secretly or openly, that diagnostic and even medico-legal problems may consequently arise, and that some qualitative and quantitative tests will then be required. This substance forms very readily with methylene-blue an addition compound, similar to that formed by picric acid, and crystallizing out quickly in fine bronze-coloured crystals. The test based on this phenomenon is performed as follows. The urine is acidified with sulphuric acid and extracted with chloroform, permanent emulsions being avoided if possible. The extract is mixed with calcium carbonate and methylene-blue, and is well shaken until the first change of colour is observed. It is then filtered, and an equal amount of distilled water is added. After further shaking the water is removed; if the chloroform shows a distinct green colour which cannot be extracted by further washings with water, α -dinitrophenol is present. The detection in the blood of a non-jaundiced person is still more sensitive. The quantitative method is based on the author's procedure for the volumetric determination of picric acid and methylene-blue. Bolliger points out why the test of urine for dinitrophenol poisoning used during the war is not applicable to gastric contents, or the blood or tissues, and may be unsatisfactory in the case of urine after the oral ingestion of α -dinitrophenol. He cites a case in which this was experimentally demonstrated.

493 Typhus Infection of Rats

I. L. KRITSCHESKI and N. N. SOŁOWIOW (*Zentralbl. f. Bakt.*, April 5th, 1934, p. 232) examined the blood serum of 103 wild rats in Moscow, and found that twenty-nine of them gave a positive Weil-Felix reaction. A living *proteus* X 19 strain was used, and in the majority of instances agglutination was of the finely granular type. The titres varied from 1 in 10 to 1 in 500. To ascertain whether the animals were infected with the typhus virus or merely with *proteus* X 19, brain suspensions were prepared from six of the rats having agglutinin titres of 1 in 100 to 1 in 500, and inoculated intraperitoneally into male guinea-pigs. One of these developed a febrile reaction and orchitis, thus showing that one at least of the rats was infected with the typhus virus. Examination was then made of seventy white laboratory rats that had been bred in the neighbourhood of Moscow. No fewer than twenty-nine gave a positive Weil-Felix reaction, the titres varying from 1 in 10 to 1 in 200. The brain of one animal with a titre of 1 in 200 was tested by guinea-pig inoculation, and was found to contain the typhus virus. K. SUZUKI (*ibid.*, p. 236), working in Hamburg, found that five out of ten wild rats had a positive Weil-Felix reaction. The brains of all ten rats were tested by guinea-pig inoculation, and the typhus virus was demonstrated in two of the positive and one of the negative-reacting animals. Both groups of workers conclude that latent typhus infections occur in rats.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

494

Mercurial Poisoning

I. M. RABINOWITCH (*Canadian Med. Assoc. Journ.*, April, 1934, p. 386) emphasizes the fact that no mercurial compound, inorganic or organic, is harmless. All can be toxic, and their value in therapeutics appears to depend largely upon their conversion from potentially into actively toxic products. Mercury is readily absorbed from all surfaces, including the intact skin, signs of poisoning having been noted within twenty-four hours after the application of mercurial ointments. Rabinowitch has had no difficulty in detecting mercury in the faeces within forty-eight hours after painting the healthy intact skin of the abdomen with mercurochrome. Its wide distribution in the body is probably due to the fact that the albuminate which mercury forms by combining with protein is soluble in the alkaline chlorides of the body fluids; the findings are not always uniform, however. Much may remain localized in the tissues owing to the formation of insoluble compounds, and the existence of these is probably the cause of its slow elimination. The clinical signs of poisoning are due to the effects of mercury on the excretory organs; its elimination is not necessarily influenced by its deposition, for in acute poisoning little may be excreted in the urine when the metal is concentrated in the kidneys. Mercurial toxicity is not related to the amount present, but to its solubility, and a most important contributing factor is the degree of ionization. The favourable effects of organic mercurial compounds in septicæmia appear to depend to some extent, at any rate, on "shock reaction." Diuresis, cathartic action, and antiseptic properties seem to depend largely upon conversion of the organic compound into a soluble inorganic and ionizable compound, a change which may explain its antisiphilitic action. Such a conversion takes place with greater ease in the case of metallic mercury. The author considers that more effective legislation is necessary as regards the standardization and sale of commercial mercurial compounds in tablet form. Moreover, the signs and symptoms of poisoning may be misleading, the initial pain, vomiting, albuminuria, and hæmaturia being succeeded for a few days by apparent convalescence, after which fatal sequelæ develop rapidly. It is therefore held to be inadvisable to discharge from hospital in less than two weeks patients admitted for mercurial poisoning. During this period blood urea examinations should be made daily in order to detect the earliest signs of grave renal involvement.

495 Pancreatic Disease associated with Diabetes

A. LUNDBERG (*Nord. Med. Tidsskrift*, April 14th, 1934, p. 460) comments on the tendency to concentrate attention on the islands of Langerhans in connexion with diabetes to the exclusion of the other constituents of the pancreas, although in hardly any disease are these islands alone involved. At the St. Erik Hospital in Stockholm 4,721 post-mortem examinations were made in the period 1925-32, and among them were 540 in which morbid changes were demonstrable in the pancreas. Yet only in ninety-one of these cases had diabetes been diagnosed. As blood sugar determinations had not been made, several cases of diabetes had assuredly been overlooked. Among the 540 cases were thirty-five of pure atrophy of the pancreas, which in twenty-nine cases had provoked a clinically demonstrable diabetes. Only nine of these thirty-five patients were men, and the average age was 65 years. Atrophy combined with lipomatosis of the pancreas was found in thirty cases, in only nineteen of which had diabetes been diagnosed. There were as many as 284 cases of pure lipomatosis, in only twenty-four of which had diabetes been diagnosed. Universal lipomatosis existed in fifty-six cases, five of which had been

recognized as diabetic. Chronic liponecrosis was found in forty-three cases, and purulent pancreatitis in seventeen, only one of which was also diabetic. Pure cirrhosis was found in eighteen cases, stone in the pancreatic duct in seven, and malignant disease in seventy-three cases, in forty-eight of which the disease had probably started in the pancreas. These observations show that pure lipomatosis of the pancreas is the most common of the diseases overtaking it (52.6 per cent. of all the author's cases), and that malignant disease comes next with 8.9 per cent. If it be asked, in a case of diabetes, what are the diseases of the pancreas most likely to be associated with it, one might answer, on the basis of the author's material, that in 31.8 per cent. the diabetes would be accompanied by atrophy of the pancreas, in 26.4 per cent by lipomatosis, in 20.9 per cent. by a combination of both, and in 9.9 per cent. by cirrhosis.

496

Tuberculosis and Dementia Præcox

A. ALBANE (*Thèse de Paris*, 1934, No. 153), who records thirty-five illustrative cases in patients aged from 11 to 46, states that tuberculous manifestations often precede the development of mental symptoms in dementia præcox. The latter usually arise when the tuberculous lesions are subsiding, and may disappear, on the other hand, when the lesions are roused into fresh activity. This is the reason why tuberculous lesions often do not arouse attention in the course of dementia præcox, except in the final stage. Systematic inquiry should, he states, be made into the patient's antecedents, and combined examinations carried out by radiological, biological, and humoral methods. The tuberculous lesions vary, and consist of pleurisy, pulmonary involvement, and glandular enlargement. Tuberculosis does not by any means account for all the cases of dementia præcox, for there are many cases of dementia præcox due to a different toxi-infectious origin.

Surgery

497

Testicular Seminoma

According to P. BLÜMEL (*Brun's Beitr. z. klin. Chir.*, March 14th, 1934, p. 227) many seminomata of the testicle have formerly been confused with carcinoma, sarcoma, or endothelioma, and probably at the present day a certain number of testicular tumours, owing to their rapidity of metastasis, are overlooked or regarded as 'secondary'. In the last twenty years' experience of the Göttingen Universitätsklinik, tumours of the testicle have been very rare (0.8 per 1,000 admissions). Of thirty-two tumours, twenty-two were seminomata according to the classification of Oberndorfer. Because of the patients' lack of observation or the difficulty of early clinical diagnosis, no fewer than five of the twenty-two patients first sought treatment for pain due to metastases, and four more had metastases on admission, so that almost one-half had secondary tumours when first coming to notice. Metastases by the lymph channels affect the inguinal much less commonly than the iliac and aortic glands; those reaching the liver and lungs by the blood stream are early. It frequently happens that important signs and symptoms such as oedema of a leg or uretero-renal colic are caused by impalpable metastases. Blümel believes that in future the Aschheim-Zondek test will play an important part in the diagnosis of testicular tumours, and more especially their metastases. (Zondek was the first to describe, and many others have confirmed, the presence of prolan A or prolan B in the urine in cases of testicular tumours.) Prolan A in the male urine seems not to denote more than a derangement of gonad-hypophysis relations, and has been found in non-neoplastic morbid conditions of the testis. Prolan B (giving Grades II and III of the Aschheim-

Zondek pregnancy test in the injected mice) has been found, when sought, in the urine of patients with chorion epithelioma of the testis, and in about two-thirds of cases so far reported of seminoma: according to Oberndörfer seminomata may contain small islets of chorion epitheliomatous cells. Prolan B was excreted by one and prolans A by the others of Blümel's three patients with seminoma. The primary tumour in the first case was composed of young cells and resembled a medullary carcinoma: a metastasis removed post mortem gave Grades I, II, and III of the pregnancy reaction. In one of the other cases prolans A disappeared from the urine after intensive x-radiation of metastases: later it reappeared and a secondary tumour (the only one now demonstrable) was found radiologically in the lung. The treatment of a seminoma consists in removal of the primary tumour, in x-radiation by large doses of the homolateral iliac and aortic lymph glands, and in repeated local irradiations of metastases under control of the Aschheim-Zondek test. Rapid disappearance of cutaneous, glandular, or even thoracic metastases after radiation is characteristic, and is accompanied by marked general improvement: one of Blümel's patients so treated survived for three years.

498

Hernia and Occupation

L. G. LORENZO (*Rev. Med. de Barcelona*, March, 1934, p. 195) roundly denies that strain or effort can cause hernia either of the indirect inguinal, femoral, or umbilical type. In proof of this assertion he calls attention to the rarity of herniae of any kind among athletes in whom the effects of violent effort take the shape of fractures, dislocations, injuries to joint cartilage, and arthritis. Though a very violent effort may rend the abdominal wall, burst the peritoneum, and thus "forge" a hernia, surgical literature does not provide any instance of such a case. In the wide experience of the writer as referee to many indemnity insurance companies, both Spanish and foreign, he has met with only one case of hernia which could be attributed to industrial accident, and this was through the fibres of the external oblique muscle, and above and lateral to the inguinal canal—in other words, a "direct inguinal hernia." To prove that sac formation is not a matter of minutes but of months or even of years, he cites the experiments of Scarpa and Moro, which show that the peritoneum is far too elastic to be moulded into a sac by a violent effort. Hence the presence of a sac definitely excludes all possibility that strain could have produced the hernia. In estimating the accident factor in any given claim for compensation for hernia, the history of pain, size of the swelling, and the time at which work was abandoned are not of the smallest value.

499 Tuberculous Arthritis of the Knee in Children

Professor MAFFEI (*Le Scalpel*, April 7th, 1934, p. 469) describes his results in a series of cases of tuberculous arthritis of the knee which were treated by conservative resection. The operation consists of extensive exposure of the joint, resection of the ligaments and cartilages, careful dissection of the synovial membrane from the front to the back, and complete resection of all the articular surfaces. Curetting of all the diseased foci is then carried out, particular care being taken in the intercondylar fossa. The bony surfaces are then placed in apposition, the lateral ligaments are sutured, as also is the tendon of the patella, and the wound closed. Fourteen cases are reported which were treated by operation. Of these eleven were considered to be cured, as the children could walk well. In one case the condition was improved, and in two instances the children died immediately after operation from shock and loss of blood. In the majority of cases the onset of the disease was insidious, with swelling of the knee, pain, and limitation of movement as typical symptoms. Rest in bed or in plaster brings relief of pain, but further attacks occur at varying intervals. Palliative treatment will sometimes bring about complete ankylosis, but frequently this is only partial, and recurrence of symptoms may take place which may require months or even years of treatment to correct. It is suggested that if after six months attempts to obtain a movable

joint by palliative treatment have failed, operative treatment should then be carried out to obtain a surgical ankylosis.

500 Pharyngo-laryngeal Emphysema after Excision of Lung Tissue

P. CLAIRMONT (*Zentralbl. f. Chir.*, April 7th, 1934, p. 821) describes a case in which, twenty hours after resection of a tumour involving the three lobes of the right lung the patient died suddenly from asphyxia preceded by cutaneous emphysema. Necropsy showed little affection of the mediastinum but complete obstruction of the upper airway by emphysematous swelling of the pharyngeal and laryngeal mucosa. Tracheotomy, but not mediastinotomy (which had been planned), might have saved the patient's life. The complication is ascribed to the fact that after the lung surface had been attached in the pleural window tight tamponage with elastic application had been done and the surface, after the dressings had become soaked became airtight. When closure of the wound is impossible, loose dressings, frequently changed, are therefore to be recommended.

Therapeutics

501 Vapour Baths in Treatment of Urticaria

A. MARCHIONINI and B. KÖRTH (*Münch. med. Woch.*, April 20th, 1934, p. 589), having noted a case of appearance of urticaria in connexion with sweating, found that in other urticarial patients induction of sweating failed to bring out a rash, but might improve an existing one. Accordingly, they were led to use vapour baths in treatment of urticaria. In most cases one or more exposures of twenty to thirty minutes to a temperature not exceeding 50° C. were successful. The cases included chronic and recent ones (many had resisted diverse treatments given before) as well as serum urticaria. The efficacy of the treatment is ascribed partly to excretion of toxic substances in the sweat and partly to the abrupt oscillations which are induced in the acid-base equilibrium.

502 Arseno-autohaemotherapy in Syphilis

A. ALECHINSKY and M. CRAPS (*Le Scalpel*, April 28th, 1934, p. 597) advocate arseno-autohaemotherapy in those syphilitic cases, apparently cured, but in which the Wassermann remains positive despite intensive treatment. In this procedure the syringe is first charged with the dose of the arsenical medicament; into this 10 to 15 c.cm. of the patient's blood is aspirated, and the mixture is immediately injected into the gluteal muscles. Treatment is given every two to four days according to the dosage employed, in series of 12, 15, to 20 injections. Intervals of three or four weeks should elapse between each series. Negative blood reactions have been obtained in some cases after the fourth injection, in others after the eighth or tenth. Short notes of three cases are given. Besides these about twenty patients are under observation who at present give analogous results. The authors state that the mixture of blood and the arsenical preparation forms an only slightly toxic combination, and that this method is beneficial in cases resistant to arsenic, and permits of a subsequent increase of dosage.

503 Blood Transfusion in Influenza

A. TZANCK (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, April 23rd, 1934, p. 535) records good results following blood transfusion in influenza and its complications. Histories are given of two cases in which rapid cure was obtained by this method. The condition of both patients was very grave, and associated with pulmonary involvement. In one case, after withdrawal of 200 grams of blood, a transfusion of 80 grams of blood was given, and two later ones of 100 grams and 70 grams respectively. An intense rigor ensued, but in a few hours marked improvement occurred. The blood donor (Group IV) was

not a convalescent from influenza, but was the only member of the family that escaped the disease. Tzanck suggests that this donor was particularly resistant, and his blood, therefore, more efficacious. The condition of the other patient not permitting bleeding, a transfusion of 100 grams was at once given. Though marked improvement followed, dyspnoea persisted. A blood withdrawal of 150 grams was then made and a further transfusion of 100 grams given. The donor was the husband (both wife and husband were Group II), who was the only member of the patient's entourage escaping infection. After the last transfusion a rigor occurred, followed by profuse sweating. During the night the temperature dropped to normal with disappearance of all clinical symptoms; this might have been merely coincidental with a pneumonia crisis. Two other cases are mentioned in which sera of convalescents from influenza were given; the favourable results in these were, however, not more marked than when ordinary donors were employed. Tzanck considers that the term "immuno-transfusion" is erroneous except in immunizing diseases. In recurrent infections, as pneumonia, streptococcaemia, etc., the reasons for the efficacy of blood transfusions are quite different and depend on complex reactions; in these cases, therefore, he prefers the term "phylacto-transfusion."

Radiology and Electrology

504

Short-wave Diathermy

J. and V. GARCIA DONATO (*Crónica Médica*, February 15th, 1934, p. 83) divide the effects produced by short-wave diathermy on the human organism into two groups—namely, those produced by the rise of temperature in the tissues traversed by the current, and, secondly, those which we may term specific and peculiar to Hertzian waves. The primary effect of the application of short-wave diathermy is a gradual rise of body temperature to 3° or 4° C. above normal, with increase of the intravenous and intrathecal pressure, while at times the arterial tension may fall by as much as 3 or 4 cm. Later, metabolic alterations are much reduced, and the chemistry of the urine is affected in various ways. The authors use the short wave therapeutically for its trophic effect in the different alopecias; for its hypotensive effect in angina pectoris, hemiplegias, and headaches; and for its analgesic properties in arthritis, neuritis, and neuralgias. They find that by far its most useful function is the production of artificial fever as a substitute for malaria therapy in the treatment of G.P.I., tabes, and the Parkinsonian syndrome. In this field the greatest possible care must be taken to keep the patient's skin perfectly dry and free from sweat, and to effect this there is now devised a method of exposing the body to a current of air at 60° C. While this is in operation the internal temperature may be maintained at 40° C. for two, or even three, hours, after which the patient is wrapped in blankets and removed to bed. The treatment is contraindicated by the existence of aneurysm, uncompensated heart disease, great hypotension, pulmonary tuberculosis, and varicose veins.

505

Radiotherapy in the Relief of Pain

J. HAGUENAU, L. GALLY, and D. LICHTENBERG (*Presse Méd.*, April 4th, 1934, p. 531) advocate deep radiotherapy in essential algias; it is ineffective in cancer pain and unnecessary in symptomatic or secondary algias. They utilize an apparatus with a constant current of 200,000 volts, filters of 1 mm. of copper, 2/10 mm. of aluminium, and a skin anti-cathode distance of 40 cm. Total doses of 3,000 r (French) are given in bi-weekly doses of 500 r (this is important) per field of irradiation. After an interval of three to four weeks the same treatment is repeated in cases of failure or in complete results. A Coolidge standard ampoule enclosed in a tube of oil is used; this to a depth of 10 cm. gives 43 to 45 per cent. of the cutaneous dose. The fields irradiated should be large to avoid

multiple ports of entry and double doses on the skin; filters of heavy metal (their irradiation supplements that of the ampoule) should be used. Each application should be relatively short, and given in a pure atmosphere at a distance from the high-tension generators. Adrenaline and jaborandi extract are useful sedatives of the vago-sympathetic reactions. The following conditions have been treated by this method. The three types of sciatica—the high (irradiation from the first lumbar vertebra to the sacrum), the median (irradiation of the sacro-iliac region), and the low (irradiation over the sciatic notch). Of thirty-one cases, fifteen showed cure, seven improvement, and nine failure. In ten cases, with six cures, two improvements, and two failures, of cervico-brachial neuralgia, the region of the roots of the brachial plexus and the supraspinous region were irradiated. Radiotherapy is ineffective in trigeminal neuralgia, but is most beneficial in facial sympathalgia (neuralgism, facial caisalgia); of twenty-one cases, nine were cured, four improved, and eight showed no result. Talalgias respond remarkably to radiotherapy; only one of five cases showed no benefits. Of two cases of coccygodynia, one was cured and the other showed little improvement. Early radiotherapy in zona was very efficacious, seven cures and one amelioration occurring in nine cases. This treatment is of no avail in post-zosterian algias of one or more years' duration. Cure or improvement was obtained in cases (including four of Paget's disease) due to osteitis and periostitis. Improvement was also noted in a case of acroparaesthesia of the arm, and one of trophodema of the leg. All the results recorded occurred in patients treated more than two years previously: the cures are therefore apparently definite.

506 Physiological Effects of Ultra-violet Radiation

As the result of the controlled investigation of two groups of healthy women during the winter months of 1930-2 HOPE H. HUNT and JANE M. LEICHSENKING (*Radiology*, March, 1934, p. 318) found that the normal individual seemed to have powers of compensation sufficiently great to counteract any stimulation resulting from ultra-violet radiation within ordinary limits. The more nearly the person approached the physiological normal, the less evident were the effects from such exposures. The use of cod-liver oil and vitamin preparations was forbidden. One half of the group each year (six cases) received ultra-violet radiation after the weekly observations had been made and blood samples taken; the control group received no radiation. During the second year treatments were given twice instead of once a week, and the subjects received respectively three times the amount of radiation given in the previous year. The production of haemoglobin appeared to be more pronouncedly affected during the second year than the first, although the effect did not continue indefinitely. It was not determined whether this increase was real or apparent and due to the temporary mobilization of the haemoglobin reserves of the body. In both test and control groups there was a slight rise in the average total red cell count, and the colour indexes of all increased from autumn to spring. The body temperature, pulse rate, and respiration to fluctuate independently of the the first experimental periods the average systolic and diastolic pressures of the control group showed a slightly greater decrease than those of the irradiated group. In the second year the decreases were almost the same. The total white counts seemed to be less influenced by the ultra-violet rays than were the other factors. During the first year the average percentage of the polymorphonuclears of the irradiated group increased and the lymphocytes diminished, but the reverse was true in the second year. With the greater amount of irradiation in the second year the liability to catarrhal infections appeared to be diminished. There was no manifest effect on sleep, appetite, weight, physical efficiency, or the type or regularity of the menstrual flow. The authors suggest that the well-known salutary results of ultra-violet therapy in disease are attributable to some action on the parathyroid glands.

Obstetrics and Gynaecology

507

Urethral Stricture

H. WYNN (*Amer. Journ. Obstet. and Gynecol.*, March, 1934, p. 373) has measured the meatus in 206 women without, and 172 with, urinary symptoms. He refers to a case of double stricture relieved by dilatation. Pathological specimens are few and signs uncertain, except for oedema, inflammation, scar tissue, and neoplasms, but reduction of the calibre by urethritis is not true stricture. The meatus being the narrowest portion of the urethra, a sound that will pass this without injury is taken as the measurement of the normal calibre of the urethra. The size of the majority is 23 to 30 F. (French bulb bougie). Gonorrhoeal urethritis is the commonest cause of stricture. Pregnancy, faulty catheterization, passage of stone, fulguration of caruncle, accidental injury, and radium application for carcinoma of cervix are other causes. Stricture occurs most commonly in the lower third of the meatus. Treatment is by incision of the meatus itself, if constricted. Dilatation under cocaine, with Hegar's dilators, relieves most cases of simple urethral stricture, but treatment has to be continued for several weeks. Burning urination and frequency are the commonest complaints. Difficulty and slowness in voiding with aching about the bladder or mental area, dyspareunia, and enuresis occur.

508 Evipan Anaesthesia in Gynaecology and Obstetrics

F. LANGSTEINER (*Wiën. med. Woch.*, April 14th, 1934, p. 447) reviews his experiences of intravenous injections of sodium evipan in various gynaecological and obstetrical conditions, and finds that the anaesthesia it induces is so satisfactory that he would no longer wish to dispense with it in certain cases. But there are limitations to its usefulness. It is contraindicated after 50, as after this age irregular breathing and post-narcotic excitation are apt to supervene. Cachexia is a contraindication, and caution should be exercised in liver disease, although the only effect it is likely to have on the anaesthesia is its prolongation. Disorders of metabolism are also a signal for great caution. Caesarian section is probably more satisfactorily performed under evipan than any other form of anaesthesia. In normal labour it is a disadvantage that evipan eliminates the pressure of the abdominal muscles when the child's head is being born. Matters are different when forceps are employed, and hitherto the author has had only the best of results with evipan in forceps deliveries. Quite small doses may be sufficient in these circumstances provided much time is not lost on suturing after an episiotomy. The complete retention of its expulsive forces by the uterus during such labour is an important point in favour of evipan, and the author has hardly ever known it to be followed by that atony of the uterus which so often is a sequel to ether anaesthesia for a forceps delivery.

509 Biological Diagnosis of Pregnancy: Modification of Friedman and Laphan's Test

Owing to the difficulty presented by the variation of the calibre of the marginal veins of the rabbit's ear after it has been injected more than once, J. DE FILIPPI (*Semana Médica*, March 15th, 1934, p. 823), substituting the intraperitoneal for the intravenous route, succeeded in making a correct diagnosis of pregnancy in fifty consecutive cases thus treated. On any day after the fourth following upon the last menstrual period, the woman, having refrained from liquid dietary for the previous twenty-four hours, and having micturated upon retiring on the previous night, gives a catheter specimen of the early morning urine which is received into a sterile container. This sample, if placed in a refrigerator, will remain active for a week and may thus be sent to a distance. A doe rabbit, isolated for the previous three weeks to prevent pregnancy and ovulation, and over four months old, weighing from 900 to 1,800 grams, receives over a period of forty-eight hours

six injections, each of 4 c.cm. of the urine intraperitoneally. Forty-eight hours after the final injection the rabbit is killed and the ovaries inspected. If naked-eye examination discloses the presence of one—or, more often, numerous—haemorrhagic follicles, round in shape, and about 2 mm. in diameter, and varying in colour from pink to wine red, the test is positive of pregnancy. Usually the result is more obviously manifest in one ovary than in the other.

Pathology

510 Triboulet's Test for Tuberculous Ulceration of the Intestines

G. HERTZBERG (*Norsk Mag. f. Laegevid.*, April, 1934, p. 402) has compared the findings of Triboulet's test with those of the x rays and post-mortem room between February, 1933, and January, 1934, at a hospital in Bergen, where his material consisted of 255 cases of tuberculosis. In ninety-nine of the 105 cases controlled by x rays the findings coincided with those of Triboulet's test (both positive in ninety-four and both negative in five). Among the thirty-nine cases coming to necropsy were thirty in which both Triboulet and post-mortem findings were positive, five in which both were negative, and four in which Triboulet was negative and the post-mortem findings positive. In consideration of (1) the commonness (over 80 per cent. according to some authorities) of tuberculous ulceration of the intestines in phthisis, (2) the possibility of curing such ulceration if diagnosed early, (3) the lack of characteristic signs, and (4) the simplicity of this test, they consider it deserves more attention than it has hitherto received. The test is performed as follows. A lump of faeces as large as a walnut is dissolved in 20 c.cm. of distilled water and filtered; 3 c.cm. of the filtrate is diluted with 12 c.cm. of distilled water; 20 minims of Triboulet's reagent (sublimite 3.5, acetic acid 1, aqua dest. ad. 100) are added. As a control the same solution is prepared without Triboulet's reagent. The test tubes containing the two solutions are well shaken, and are compared after five and twenty-four hours. A positive reaction is indicated by a cloudy grey or brown deposit, above which the solution is clear. The presence in the bowels of large quantities of water-soluble serum proteins derived from tuberculous ulcers is said to be indicated by such a positive reaction.

511 The Staining of Acid-fast Bacilli

J. W. FIELDING (*Aust. Journ. of Exper. Biol. and Med. Sci.*, March 16th, 1934, p. 1) records the results of investigations undertaken to explain the loss of acid-fast staining properties in bacteria, and to find a method to correct it. When these bacilli are present in tissues preserved in formalin or otherwise, they may frequently fail to take the stain, and are consequently overlooked, the two least harmful fixatives in this respect being those of Zenker and von Rath. Fielding is satisfied that neither formalin nor alcohol used as a fixative is responsible for the permanent destruction of acid-fastness in bacilli, nor is this acid-fastness abolished by formalin or acetone, or treatment with both. Ehrlich's original observation regarding the necessity for the alkaline treatment of acid-fast bacilli would appear to be sound. Fielding believes that autolytic action in the tissues is primarily responsible for lowering the pH value of the fixative, and that such low values are responsible for the change in staining reaction. It follows that an attempt should be made to keep the pH value of the fixative on the alkaline side; alternatively, an alkaline fuchsin preparation may be used for staining. Fielding gives a formula for such a stain: sodium bicarbonate in 0.25 per cent. concentration being mixed with basic fuchsin dissolved in absolute alcohol. He adds that a comparison of the relative values of an alkaline and an acid formalin fixative revealed evidence in favour of the former. The alkaline fixative contained 0.5 per cent. sodium bicarbonate in 10 per cent. formalin.

EPITOME OF CURRENT MEDICAL LITERATURE

Medicine

512 Chronic Idiopathic Steatorrhoea

M. SNELL and J. D. CAMP (*Arch. Int. Med.*, April, 1934, p. 615) record seven cases of fatty diarrhoea with associated changes in the metabolism of calcium and phosphorus; radiological studies of the gastro-intestinal tract were made in all except one, and in four definite abnormalities in the contour and motility of the small intestine were thus revealed. These findings suggested the presence of an inflammatory condition, with oedema of the mucosa and infiltration of the walls, involving especially the small intestine, but occasionally also the stomach, duodenum, and colon. The regression of the changes coincident with improvement in the clinical symptoms and inflammatory changes described in necropsy reports of similar cases seem to substantiate this opinion, and to indicate the lines of treatment. The alimentary tract should be rested; the blood should be restored to normal; and such deficiencies as lowered concentration of calcium and phosphorus in the blood and defective gastric secretion of hydrochloric acid should be remedied. In some cases restriction of the dietary intake of fat coupled with increase of the protein intake will afford relief. Tolerance to fat appeared to be variable, some of the patients in the authors' series taking up to 100 grams daily, while others were unable to utilize half this amount. Such limits of tolerance indicate the necessity for patients to be treated at first in hospital, where the intake and excretion of fat can be measured and compared. The use of vitamin D in the form of viosterol appeared to be of great therapeutic value, in some cases keeping the diarrhoea and the depletion of calcium under control. Parathyroid extract is only a symptomatic remedy in these cases, since it does not increase the utilization of calcium, but only causes increased liberation of this from the skeleton. It had little effect on the diarrhoea, but was useful in controlling tetany. For the anaemia liver extract was employed with good results in some cases, but one patient was at first made worse by it. The prognosis of this condition appears to be fairly good; even if the bones show extensive demineralization the outlook is not necessarily hopeless. The first essential is to evaluate early the aetiological factors in the individual case, and to devise the treatment accordingly.

513 Hyperpiesis and Expectation of Life

E. MASING (*Deut. med. Woch.*, April 20th, 1934, p. 591) publishes figures which, he claims, show that the expectation of life in hyperpiesis is greater in a quiet German town than in the more feverish atmosphere of Western Europe and North America. His observations cover a score of years in private practice, in the course of which he has observed and subsequently followed 161 cases in which the systolic blood pressure at the first examination was not under 150 mm. Hg. In some of the cases this pressure was over 140 at the first examination, rising higher at a later date. Eighty patients had since died, and eighty-one were still alive. The average age of the dead patients were 57.3 years when their hyperpiesis was first detected, and their average age at death was 64.9 years. According to the calculations of German life insurance societies, the expectation of life of a healthy man of 57 is 14.3 years. About 70 per cent. of all the deaths were due to the hyperpiesis (cardiac insufficiency and circulatory disturbances in brain, heart, and kidneys). Among the eighty-one survivors kept under observation for not less than six years, and for an average of 10.6 years, were thirty-three who were fully fit for work, although some might occasionally suffer from some dis-

comfort. Thirty-seven were more seriously hampered, and eleven were more or less seriously ill. The author suggests that there may be a certain antagonism between hyperpiesis and cancer, to judge by the rarity of the latter in his material, both living and dead. As for the treatment of hyperpiesis, he is lukewarm in his advocacy of drugs, and the remedy he considers most potent is rest in bed. It may bring the blood pressure down in a few days from 200 to 125, and when a high blood pressure is but little influenced by this treatment the prognosis is, as a rule, bad.

514 The Mean Arterial Pressure

F. R. VAN DOOREN (*Le Scalpel*, April 21st, 1934, p. 542) presents a study of the mean arterial pressure in some 230 cases, first reviewing previous work on this subject. As he has already proved that puncture of an artery regularly gives a pressure reading identical to that of the oscillogram, this method was employed. The pressure calculated by the sphygmomanometric curve at the humeral artery was compared with that obtained by puncture of the same artery and by puncture of the radial, femoral, and dorsalis pedis arteries of the same side. In 70 per cent. of these readings the mean pressure was the same by both methods; differences, when present, were due to a lowering of the arterial-puncture values; the difference was less between the pressure values at the humeral and radial than those at the humeral and femoral. It has been demonstrated that a very slight but regular and progressive tensional drop occurs from the large vessels to the periphery; Tiegestedt has stated that, despite this drop, the pressure is everywhere the same. The present researches confirm this view, and also confirm the value of the mean pressure in only 70 per cent. of the cases, the remaining 30 per cent. being inexplicable. A study of the maximal, minimal, and mean pressures in these cases shows that the concordances between the two former are scarcely apparent, while between the minimal and mean they are almost constant. The difference between the latter two pressures in normal subjects was 1.6 cm. of mercury, in atherosclerotic conditions 3 to 4.3, and in cardiac insufficiency 2.6. The last-named is therefore only one factor of rise in the mean pressure, induration of the vessels being a much greater one. Van Dooren asserts that a rise in the mean pressure corresponds to one in the minimal, and that occasionally the former is without change in the latter. He concludes that the mean pressure corresponds to nothing explicable, and that its name characterizes a tensional value impossible to justify. Its dependence on the minimal pressure gives it a semblance of reality, but the faulty technique which has been previously employed cannot furnish strictly uniform results.

515 Diabetes and Exercise

J. A. COLLAZO and J. BARBUDO (*La Med. Ibera*, April 14th, 1934, p. 453) state that a study of the literature shows the undoubted clinical fact of an increased tolerance for carbohydrates in diabetic patients in the acute stage who exercise their muscles (by manual work, sport, gymnasium, massage, and the like). In those cases in which an equilibrium has been obtained by insulin the dose of the drug can be reduced. In twenty-one cases of diabetes in which the curve of hyperlactacidaemia following exercise was investigated, the writers found that: (1) in almost all cases there was a rise of lactic acid in the blood by about 4 mg. above the normal, and (2) that the glycaemia showed a distinct fall in all these cases. They attribute these results to a better utilization of circulatory glucose by the muscles, and a greater avidity of the hepatic cell for the lactic acid of the blood.

Surgery

516 Intrathoracic Tumours of Neural Origin

M. MAKKAS (*Brunns' Beitr. z. klin. Chir.*, March 14th, 1934, p. 276) gives an account of two personal cases and twenty-six from the literature of operation for intrathoracic neural tumour, comprising ten ganglioneuromata, nine neurofibromata, eight neurinomata, and one sympathetico-blastoma. With the exception of one neurofibroma, which had become sarcomatous, all were benign: all but one were found in the posterior mediastinum (usually high up), and three out of four affected females. There was no special age incidence, except that ganglioneuroma in the great majority of cases occurred below the age of 20. The source of the tumour was frequently undetermined, but appeared as a rule to be the sympathetic cord or an intercostal nerve. The largest diameter of the tumours ranged from 3 to 20 cm. Clinically, a long history (two to twenty years) of slight and indefinite symptoms was usual—slight pain, dyspnoea, or dry cough. Intercostal neuralgia was reported in two cases only. Physical signs of dullness and impaired air entry led to suspicion of chronic pulmonary or pleural inflammation in most cases; but diagnosis was sometimes aided by detection of a supraclavicular extension of the tumour (four cases) or a unilateral ptosis and myosis pointing to sympathetic palsy. In no case was diagnosis made before radiography, but in no case did this fail to show the tumour; however, it was not seldom regarded as being probably a dermoid or hydatid cyst. Differential diagnosis from malignant tumour is not long difficult. From a dermoid cyst, which also has a sharp, rounded outline, neurogenous tumours are distinguished by their occurrence in the posterior mediastinum: from a hydatid cyst by their broad inner margin, flat or non-concave internally towards the vertebral axis, and by the negative Casoni reaction. At operation posterior mediastinotomy is preferable; the tumour shells out without difficulty, and serious haemorrhage has not been noted. Opening of the pleural cavity is usually unavoidable. Sauerbruch recommends that in operations on tumours of sympathetic origin a posterior portion should be left behind—otherwise a lethal tachycardia may occur. The mortality in this collected series was 32 per cent., and pleuro-pulmonary complications followed in about one-half.

517 Vesiculography

A. GORRO (*Journ. d'Urol.*, March, 1934, p. 193) points out the difficulty previously experienced in obtaining an x-ray photograph of the seminal vesicles, which have only been visible in cases where there is a calculus or cystic lesion, or where a tumour is in the process of calcification. In order to obtain a good result it is necessary to inject a contrasting medium, and it has been found that neiodipin answers this purpose. It is neither toxic nor painful—even if remaining for some time in the seminal vesicles—while good aseptic results are obtained. It is possible to fill the vesicles by four different methods: by catheterization of the ejaculatory ducts by urethroscopy, by transrectal or perineal puncture of the seminal vesicle, by subcutaneous puncture of the vas, or by puncture of the vas by the scroto-inguinal route. Of these methods the first is often unsuccessful, the second and third are uncertain and dangerous, and it is thus by the last method that good results have been obtained. The success of the procedure depends on the technique, which the author fully describes and illustrates. The operation is carried out under local anaesthesia, a 10 per cent. solution of novocain being used. An incision is made at the root of the scrotum, and the opaque liquid is injected into the vas until the patient desires to urinate, thus showing the passage of the fluid from the vesicle into the prostatic urethra and into the bladder. This usually occurs after 2 to 3 c.cm. has been injected. The incision is closed, and the patient expels any surplus fluid. The x-ray photograph can then be taken with the patient on his back. The fluid injected often remains in the vesicular

cavity for several days, or even weeks, without causing discomfort. By this means it is possible to obtain a accurate diagnosis in cases of malignant tumours of the prostate, retro-vesicular and retro-prostatic tumours, or in chronic inflammatory conditions of the vesicles.

518 Chronic Arthritis of the Hip

C. ROEDERER and P. GRAFFIN (*Rev. Méd. Franç.*, March 1934, p. 283) divide the surgical treatment of non-tuberculous chronic arthritis of the hip into five different methods: subcutyloidian osteoplastic buttress, arthrodesis, resection, subtrochanteric osteotomy, and drilling of the femoral head. The bone graft, or buttress operation is not very satisfactory, and should be reserved for cases of arthritis in young persons when subluxation is only of moderate degree, and when the head of the femur is only slightly deformed and displaced. In other cases it is not sufficiently firm to prevent the displacement of the femur with consequent pain. Arthrodesis should only be used in cases of unilateral arthritis with severe pain and gross malformation of the hip-joint. Ankylosis is difficult to obtain in old people, and necessitates a lengthy immobilization. In cases of bilateral arthritis, ankylosis of one hip is unwise. Resection of the head of the femur is a serious operation, which should only be carried out in cases which are exclusively femoral, and are bilateral, with a tendency to ankylosis. Subtrochanteric osteotomy is a simple procedure, which gives good results. It should be used in all cases where there is poor position and when abduction is markedly limited. This operation should be performed in the majority of cases of arthritis. It does not limit the movements of the hip, and only requires two or three months of immobilization, according to the age of the patient. Drilling of the neck of the femur is also a simple operation, and immobilization is only necessary for a few days. The indications for this method of treatment are: good apposition of the hip, a lesion predominantly femoral, and the femur being in a good position. Osteotomy and drilling of the femur may be carried out simultaneously in certain cases.

Therapeutics

519 Diathermy in Alcoholic Cirrhosis

J. LEXA (*Thèse de Paris*, 1934, No. 228), who records twelve illustrative cases in patients aged from 27 to 71, three of which are original, maintains that diathermy has an undoubtedly favourable action on the course of certain hepatic affections accompanied by ascites. The most convincing results have been obtained in the treatment of alcoholic cirrhosis with ascites. According to Lexa's own experience, the cases with a large liver react best. In the atrophic and sclerotic stage diathermy appears to have less effect.

520 Autohaemotherapy in Typhus

A. BABALLIAN (*Bull. Soc. Path. Exot.*, March 14th, 1934, p. 235) treated sixteen cases of typical severe typhus fever in young men in a hospital at Teheran by intramuscular injection of 10 c.cm. of their own blood. Each injection was followed by an immediate improvement in the general condition. The treatment appeared to shorten the duration of the disease and convalescence, and did not give rise to any complications. Four to five injections were given in each case.

521 Use of Stryphnon in Haemoptysis

As the arterial pressure is always lowered while the venous is constantly raised, in haemoptysis, J. E. WOLF and J. DUCHAINE (*Bruxelles-Médical*, April 22nd, 1934, p. 807) advocate the use of an injectable styptic in this condition. They employ "stryphnon," a methylaminocetobenzocatechin, which immediately precedes adrenaline in the synthetic series; it is a white powder, soluble in water, and slightly in alcohol, and possesses great vaso-constrictive properties. The authors inject, intravenously and

very slowly, two-thirds of an ampoule containing 2.2 c.cm. of a solution of the drug (0.2 to 0.3 c.cm. is given per 10 kilos of body weight); the dose depends on the patient's resisting powers, and is less for females and those in a weak condition. The haemorrhage usually ceases at the end of the injection. In cases of very abundant haemoptysis it is advisable to give a subcutaneous injection of 1.5 to 2 c.cm. half an hour later. As strychnon raises the blood pressure, its use in hypertension is dangerous; this being its only contraindication. This drug should only be used in cases of urgency; it is useless in chronic slight haemorrhagic oozing. The authors have abandoned the use of morphine in favour of strychnon. It is less dangerous than pituitary extract, and has a more rapid action than other pulmonary haemostatics. Its action, though of a transitory duration of only an hour, is sufficient to allow of preparation for subsequent more radical treatment.

Ophthalmology

522 Local Antigonococcal Serum in Gonoblennorrhoea and other Eye Diseases

W. A. WILLE (*Brit. Journ. Ophthalmol.*, April, 1934, p. 218) instils the serum in the following manner. The conjunctiva is first irrigated with water, 1 per cent. cocaine is instilled, and the everted lids are swabbed with boric tampons. With the lids still everted, the conjunctiva is covered with serum, the lids being kept everted for twenty-five seconds. This is done four times, with intervals of ten minutes, twice a day. At home boric tampons and protargol 2 per cent. are used hourly. The treatment has proved successful in gonoblennorrhoea, Koch-Weeks conjunctivitis, trachoma, spring catarrh, and dendritic ulcer, and is equivalent to the use of 2 per cent. silver nitrate without the danger of irritation, cauterization, pain, or corneal damage. A serum reaction, which may not occur till after three weeks' treatment, if present, is slight. In such cases the remedy is often especially beneficial.

523 Two Cases of Buphthalmos in Siblings

J. HYNES (*Amer. Journ. Ophthalmol.*, February, 1934, p. 132) reviews the literature, pointing out that this condition is present at birth, and is but a major degree of the infantile type occurring in the second and third decades. The treatment is essentially surgical. Elliot's trephine, which offers a better hope of recovery than iridectomy, should be performed as early as possible, and before the age of one year. He describes two cases in sisters. The eyes were noticed to be enlarged in the first at 6 months and in the second at 7 months. Both showed a steamy cornea of large diameter, a deep anterior chamber, raised tension, and a cupped optic nerve. Trephining stopped the progress of the condition, allowing poor vision in the first and good vision in the second case.

524 Ocular Method of Determining Vitamin A Deficiency

P. C. JEANS and Z. ZENTMURE (*Journ. Amer. Med. Assoc.*, March 24th, 1934, p. 892) describe a clinical photometric method of determining moderate degrees of vitamin A deficiency, in view of the fact that night blindness is one of its manifestations. The instrument used was an electrically illuminated Birch-Hirschfeld photometer, with a Goldberg wedge permitting a gradual and uniform decrease of light transmission. The wedge is marked with a scale of opacities ranging from 1 to 13. In a series of 213 children the instrument readings in forty-five were of such a character as to indicate poor recovery of light sensitivity. In no case was any abnormality discovered other than the functional one. When the children were given three teaspoonfuls of cod-liver oil daily in addition to their hospital diet they all subsequently reacted normally to the test. The average period required for recovery was twelve days. It was observed that some of the children

with vitamin deficiency were mentally alert and apparently well nourished; others were under weight and mentally sluggish, although not mentally deficient. Still other children seemed to be suffering from nutritional deficiencies, but the dark vision tests indicated no deficiency of vitamin A. It was noted also that as a rule the vitamin A deficient children who were retained under observation improved both in physical and in mental well-being. The authors are satisfied that this test is effective in detecting moderate degrees of vitamin deficiency without difficulty or loss of time.

525 Results of Orthoptic Training

G. P. GUIBOR (*Arch. of Ophthalmol.*, March, 1934, p. 433) quotes conflicting evidence from several sources as to the age, vision, and degree of squint of favourable cases and the time required for training. He records success with patients of from 2 to 39 years, comparing the results in forty control cases where atropine, covering, or operation but no apparatus was employed with those in thirty-eight cases trained in an orthoptic clinic where no operations were performed. Of the forty controls, 7.5 per cent. were worse, 47.5 per cent. unimproved, 25 per cent. improved, 12.5 per cent. cured while wearing glasses, and 7.5 per cent. cured without glasses. Of the thirty-eight cases in the orthoptic clinic 2 per cent. were worse, 34.2 per cent. unimproved, 13.8 per cent. improved, 7.9 per cent. cured while wearing glasses, and 42.1 per cent. cured without glasses. He gives a full description of the methods employed in the orthoptic training. The average of cures by this method given by twelve other writers is 46.8 per cent. The author adds a comprehensive list of the causes of failure in orthoptic training.

Obstetrics and Gynaecology

526 Pre-natal Diagnosis of Foetal Sex

A. P. GIANGIOBBE (*Rev. Med. Latino-Americana*, January, 1934, p. 351) claims to have demonstrated foetal sex in all cases (twenty-one) on which he employed a reagent of which he is the discoverer. This is a hydro-glycerated freshly prepared extract of the testicle of the human foetus or stillborn male child, of which he injects intradermally, over the deltoid muscle of the patient, and at two points 3 cm. apart, one-half of 1 c.cm. The site of injection is examined twenty-four hours later, and if a congested macule or papule is observed the reaction is considered positive of male pregnancy. If the skin is unaffected this indicates that the embryo is female. The reaction is definite no matter at what period of pregnancy it may be practised. The injected material is sterilizable quite readily, but should not be obtained from an infected foetus. The writer has met with similar success in like experiments on uniparous lower animals, but he says nothing about sex determination in multiple pregnancies. He believes that during the child-bearing age the female passes through periods of secretory change, which he terms "masculine" and "feminine," and which are governed by laws in close alliance "with the intimate essence of life." Sex depends upon which of the two secretory conditions is active at the moment at which the ovum is impregnated.

527 Endometriosis Vesicae

R. B. PHILLIPS (*Journ. Obstet. and Gynaecol. British Empire*, April, 1934, p. 165), reporting a case of endometriosis of the bladder, points out that the condition probably occurs more commonly than his collection of twenty-nine cases would suggest. The diagnosis is frequently missed owing to the omission of cystoscopic examination. After discussing the theories of endometriosis, he describes the pathology—non-encapsulated growths, or (?) implants of endometrial tissue which invade the pelvis, often in association with uterine fibroids, enclosing areas filled with more or less altered blood, notably the chocolate cysts of the ovary. Clinically, the average age

for endometriosis of the bladder is about 40. The first complaint is of frequent, often painful, micturition coinciding with the monthly periods, and at first disappearing between-whiles. Haematuria is then noted, also cyclic. These symptoms increase in severity and persistence. The diagnosis is suggested by this history, but is established only by cystoscopy. The blue-black cysts and blue folds of oedema then seen are characteristic. The ureteral openings are displaced by growth, and bulging of the walls is seen. A piece of tissue can be obtained for microscopy. Cyclical changes in the growth can be watched by cystoscopic examination at dates near to or distant from the menstrual period. Treatment is by surgical removal when the growth is not too extensive and the patient young. At the menopausal age, x-radiation of the ovaries leads to recession of both normal and abnormal endometrium. In the case under discussion, both the vesical and the intestinal symptoms were relieved, the growth having been so extensive as to involve both.

528 Brouha's Reaction in Biological Diagnosis of Abortion

A short account of experiences in twenty-one cases with the application of Brouha's reaction in gynaecology is given by VAYSSIÈRE, CHOSSON, and DONNET (*Bull. Soc. d'Obstét. et de Gynécol. de Paris*, March, 1934, p. 248). The biological diagnosis, not only of the existence, but of the development or arrest, of a pregnancy, can now be made by the observation of quantitative reactions. The rabbit is used as being the most-reliable and convenient experimental animal; Brindeau's rabbit unit being the smallest dose of hormone which, injected intravenously into a rabbit weighing 2 kilos, produces in forty-eight hours at least one haemorrhagic point on at least one ovary. Serum or urine can be taken, the former being very constant in hormonal content. The fundamental principles of the test are: (1) that the titre of pregnancy hormone in serum diminishes very rapidly after the death or expulsion of the foetus (it appears to be connected with the quantity of living placenta in the maternal organism), and (2) that in urine there are marked fluctuations of the proportion of hormone, while in serum it is constant. In practice, fasting morning urine is comparable with the serum, and can be used under the same conditions. The following four "zones" are recognized: (1) results uncertain = up to 100 Brindeau rabbit units; (2) pregnancy interrupted = 100 to 800; (3) caution = 800 to 1,000; (4) normal evolution = 1,000 to 4,500 units. The technique consists in injecting several rabbits with doses calculated, according to clinical probabilities. In forty-eight hours the ovaries are examined. If the results are not definite enough they at least give indications of dosage for a second series of injections. Alternatively, the first stage may consist in using 5 c.cm. of urine on one animal, and, by reading the result, finding the dosage for accurate quantitative calculation in the second stage. In their twenty-one cases of abortion verified by curettage, the authors found the concentration between 100 and 800—that is, in Zone 2 every time.

Pathology

529 Studies in Pseudo-rabies

P. REMLINGER and J. BAILLY (*Ann. de l'Inst. Pasteur*, April, 1934, p. 361) report a series of experimental studies on the condition that is known variously as Anjeszky's disease, infectious bulbar paralysis, mad itch, or pseudo-rabies. Under natural conditions it affects dogs, cats, cattle, horses, pigs, goats, sheep, rats, and mice, but experimentally it can be transferred to a number of animals and birds, though cold-blood animals have proved refractory. The experimental disease is best studied in the rabbit, in which the clinical picture shows a surprising variability, encephalitic, pseudo-herpetic, meningeal, paralytic, pruriginous, fulminating, and abortive forms being

seen. The morbid-histology is still doubtful, and so far, though the disease is undoubtedly caused by a virus, the authors have failed to demonstrate inclusion bodies in the central nervous system. A valuable differential diagnostic table is given distinguishing pseudo-rabies from rabies. In rabies the incubation period is long, there is a prodromal period, the intellectual faculties are affected, there is little or no pruritus, there is a tendency to ingest inert bodies, a paralytic period during which the lower jaw is often affected is common, sudden death is rare, the disease lasts three to five days, the saliva is virulent, infection occurs by biting, there are Negri corpuscles in the brain, and the virus is pathogenic for man. In pseudo-rabies the incubation period is a matter of hours, there is a brusque onset, the intellectual faculties are preserved, there is intense pruritus often dominating the whole clinical picture, there is no tendency to ingest inert bodies, paralysis does not occur till just before death and does not affect the lower jaw, sudden death is common, the disease lasts only twenty-four to forty-eight hours, the saliva is not infective, the natural method of transmission of the disease is doubtful, there are no Negri corpuscles, and the virus is not pathogenic for man.

530 A Stain for "Inclusive Bodies" in Virus Diseases

T. HAMILTON (*Journ. Trop. Med. and Hyg.*, May 1st, 1934, p. 139) describes a method of using methyl-blue and hot alcoholic eosin 1 as a stain for "inclusive bodies" in virus diseases. The paraffin sections must be thoroughly dried on the slide in the paraffin oven at 54°C.; this prevents their detachment in the subsequent manipulations with hot stains even though the slides are not albuminized. Saturated alcoholic eosin 1 is used with 0.5 per cent. aqueous eosin 1. The stain is set alight on the slide, and allowed to burn out. The process is then repeated. Following treatment with saturated potash alum and ammoniated spirit, and watching the decolorization under the microscope (drying being carefully guarded against) until the tissues are bright pink and the red blood cells vermilion, the sections are stained for ten minutes or longer in 0.5 per cent. aqueous methyl- (not methylene-) blue, until the background viewed microscopically is a dirty blue-red and the blood cells are still vermilion. The slide is then flooded with absolute alcohol first, and next with ammoniated absolute alcohol, the ensuing differentiation being controlled with the utmost care under the microscope. This is the most important stage of the procedure, and the scrutiny must be continuous. The background will now appear very faintly blue, while the red cells and nucleoli are strongly vermilion. To naked-eye observation the section appears to have lost all its blue colour. After washing in water, and then carefully in water acidified with acetic acid till a delicate blue background returns, the sections are dehydrated, cleared, and mounted in Canada balsam.

531 Pirquet's and Moro's Tuberculin Tests Compared

R. MAGNUSSÖN (*Tidsskr. f. d. Norske Lægefor.*, May 1st, 1934, p. 469) remarks that if inunction of the skin with Moro's tuberculin ointment yielded as reliable information as the Pirquet test, the former might be preferable where mass investigations were being conducted and the testing carried out by others than doctors. Between April, 1931, and December, 1933, he applied both tests to the adult patients admitted to a public sanatorium in Norway. A combined human and bovine tuberculin of Norwegian manufacture was used for the Pirquet test and a 50 per cent. tuberculin ointment (Norwegian) for the Moro test. Among 791 positive Pirquet reactors there were only 404 giving a positive reaction to Moro. There were only four patients who were Pirquet-negative and Moro-positive. The patients were classified according as they (1) were over or under the age of 20, (2) were in the first, second, or third stage (Turban-Gerhardt) of the disease, or (3) had a normal or abnormal sedimentation rate. But in whatever way the material was resubified, no conditions could be found in which the Moro test could be said to give even approximately reliable information.

COUNCIL HOSPITALS UNDER THE LOCAL GOVERNMENT ACT

(Concluded from page 45)

Certain questions arise in connexion with the administration of council hospitals which are of special interest to the medical profession—for example, the way in which such hospitals are to be staffed and the class of patients who may be admitted to them.

MEDICAL STAFFING

If the sick continue to be treated in a mixed institution—defined in Article 6 of the Public Assistance Order, 1930, as an establishment for the reception and maintenance of the poor, other than a hospital—it must be realized that the chief administrative officer is the master, who is responsible for the "governance and control" of the institution and all its officers, servants, and inmates (Article 168). A medical officer, not holding the status of a medical superintendent, must be appointed, either on a whole-time or part-time basis, resident or non-resident. He reports direct to the house committee on matters which may appear to him to require attention. The medical records of discharged cases are, however, kept in the custody of the master, to whom the medical officer must deliver them. The subordinate position of the medical officer is obviously unsatisfactory, but where the institution is preponderantly non-medical it is difficult to see how any other arrangement is possible. The British Medical Association has made representations to the Ministry of Health that in any forthcoming amendment of the Public Assistance Order changes should be made which will secure greater independence for the medical officer and safeguard medical records from scrutiny by lay officers. In institutions where the majority of the inmates are sick, some authorities have appointed a medical man in the dual capacity of master and medical officer. This arrangement has worked well, and might usefully be followed by other councils as occasion arises. The Public Assistance Order contains an awkward provision (Article 156) that masters and matrons shall be jointly appointed—obviously intended to ensure that such officers shall be man and wife—which is clearly impracticable in cases where the medical officer is also the master, and the Minister, acting under his general power to sanction departures from the Order (Article 8), does not appear to insist upon its observance in such special circumstances.

In hospitals, properly so-called, remaining under the Poor Law, the appointment of a medical superintendent is obligatory (Article 143), and the general power to appoint such other officers as the councils think necessary (Articles 148 and 149) enables them to engage medical

staff in sufficient numbers either on a whole- or part-time basis. In modern times guardians and their successors have departed from the purely whole-time principle in staffing their hospitals, consultants and specialists being engaged to an increasing extent in their work. The resident staff, however, are usually practitioners with some previous hospital experience, and serve for much longer periods than the house-physicians and house-surgeons of voluntary hospitals, so that the consulting staff seldom carry responsibility for the routine medical and surgical work of the wards.

Under the Public Health Acts county and county borough councils have much greater freedom as to the number and type of appointments which they may choose to make, practically the only control over their actions being provided by Section 104 of the Local Government Act, 1929, which enables the Minister to withhold grants from authorities which fail to make adequate arrangements for carrying out any of their public health duties, or, alternatively, exhibit undue extravagance in doing so. It is the policy of the Association that part-time medical service should be utilized to the greatest possible extent, and county and county borough councils should therefore be urged to adopt a system of staffing which will largely free the medical superintendent from clinical preoccupations and relegate to a visiting staff the responsibility for the welfare of the patients in wards definitely allocated to them. The valuable clinical material in council hospitals should also be made available for the post-graduate experience of medical practitioners by increasing the number of short-term resident appointments, and adequate arrangements for a pathological service should be made at the hospitals. In areas where there is a medical school it is desirable that arrangements, satisfactory to the council, the medical profession, and the school, should be made for a close association of the council hospitals with the teaching of medicine.

The Association's policy is definitely that all medical service should receive adequate monetary recognition. The agreed scales of salaries for whole-time medical officers cover such officers, whether working under the Poor Law or not, and tentative scales of salary have been approved by the Representative Body for the part-time consulting staff.

THE CLASS OF PATIENTS TO BE ADMITTED

Under the Poor Law the councils are responsible only for such patients as may be regarded as destitute, but it has been pointed out in a previous article that the interpretation now put upon the term "destitution" is so wide that, at least so far as hospital treatment is concerned, practically the whole population at the national

insurance level, or about 80 per cent. in towns, fall within it. In recent times, even before the abolition of boards of guardians, Poor Law hospitals have, to a growing extent, opened their doors to persons whose other needs would certainly not lead them to seek public assistance. The transference, then, of hospitals from Poor Law to public health administration, has not created a new problem, but, merely accentuated it. Section 131 of the Public Health Act enables a council to provide hospitals or places for the reception of the sick for the use of the inhabitants of their district, and Section 16 of the Local Government Act imposes the obligation upon them of recovering the cost of maintenance up to the capacity of the patient, or of some responsible person, to pay; except in the case of infectious disease, for which the expense may, but need not, be claimed in terms of Section 132 of the Public Health Act, 1875. The cost of maintenance, as defined in the Local Government Act, includes the cost of staff and of treatment. Whether any allowance can be made for loan charges on the land and buildings does not seem to be quite clear.

It is evident, then, that any inhabitant of the district governed by the council may regard himself as entitled to admission to a hospital which it is administering under the Public Health Acts, provided that he is suffering from a condition requiring hospital treatment. It is doubtful whether this broadening of entitlement will cause any material increase in the use of hospitals by those who can afford to pay for private treatment, but much will depend upon the administrative arrangements. The voluntary hospitals are occasionally used by well-to-do persons who are able, by influence or otherwise, to obtain privileged treatment—for instance, special rooms without extra payment—and an extension of this practice to council hospitals is undesirable. It ought to be a condition of admission that no patient should receive special consideration because of his social status, and that side-rooms should be allocated on purely clinical grounds, unless special pay-beds have been set aside, the occupants of which make their own terms with the practitioner under whose care they are being treated. If these conditions are strictly observed, it is unlikely that many persons who are able to pay for privacy will seek admission to council hospitals. The provision of pay-beds in every area is, however, an important factor in the problem, and should be ventilated by the local profession. It will usually be found desirable that they should be associated with a voluntary, rather than a council, hospital; but the matter is one which might profitably be discussed in conference between the council and the local voluntary hospital committee.

RECOVERY OF THE COST OF TREATMENT

It is generally thought that the power to recover costs under the Poor Law is greater than under Section 16 of the Local Government Act, and up to a point this is true. Section 14 of the Poor Law Act, 1930, imposes the duty of maintenance on certain specified relatives, but the Local Government Act places the obligation upon "persons legally liable to maintain" a patient in a hospital without stating who these are. It is understood that such persons may be interpreted as being those defined in the Poor Law Act, but this is by no means certain. Further, even under the Poor Law Act it has been adjudged that there is no power of recovery without prior appeal to, and order by, justices of the peace. It has therefore become customary for the administrators of the Poor Law to obtain beforehand a legally binding promise of payment before claiming it, and if possible before admission to hospital. Clearly, the whole position needs review and clarification by amendment of the law. In the meantime, the point to be kept in mind is that the argument against administration of hospitals under the Public Health Acts, on the ground that the Poor Law affords better means of obtaining reimbursement, is not a very strong one to place against the undoubted improvement in service to the public and advancement in medical practice which the removal of hospital treatment from the Poor Law will bring about. As regards patients

who are not "inhabitants of the district," public health hospitals are under a disability in that they cannot recover costs from the councils of the areas of domicile unless binding agreements are in force. This question is not one of material financial consequence; but it can be, and is, freely used to obstruct appropriation of hospitals, and some amendment of the law is desirable, which will remove the burden of the treatment of an accident or sudden illness from an authority in whose area the patient or responsible person is not a ratepayer.

THE INSURANCE MEDICAL SERVICE WEEK BY WEEK

Ante-natal Examinations

The Insurance Acts Committee was asked by the Annual Panel Conference to consider the question of routine ante-natal examinations as part of an insurance practitioner's duties, together with reports thereon to local authorities. From the report of the January meeting of the committee it will have been observed that the following resolution was passed without a dissentient:

That the committee recognizes that the position has arrived when ante-natal examination and supervision is regarded as an essential service for the pregnant woman, that it is a service which can and should be rendered by general practitioners, and therefore it is a service to which insured women as such are entitled.

It is as well to observe the principle which lies behind the adoption of this resolution after a very full discussion. The Insurance Acts Committee has always interpreted the insurance service as a general practitioner service, and felt that any new developments which came along and which were within the province of the general practitioner should be placed ungrudgingly at the service of the insured patient. For the benefit of those who might be moved by practical considerations rather than by sound principles the chairman stated that, if the representatives of the profession could not go before any future court of arbitrators and say that practitioners as a whole had given a full general practitioner service, it would obviously jeopardize their claim for a favourable reassessment of the capitation fee. It should be added that it was emphasized that the resolution with regard to ante-natal examinations did not necessarily entail that reports to the authority should also be looked upon as part of the practitioner's duties without payment.

Range of Medical Service

As an illustration of the type of case which from time to time involves the question whether a service is within the scope of the practitioner's obligations, the following extract from a recent report of the London Insurance Committee is of interest:

Under Clause 10 (2) of the Terms of Service for Insurance Practitioners a practitioner is required, if he renders to an insured person for payment a service which is alleged to be not within the scope of the practitioner's obligations under the terms of service, to furnish the committee with such particulars relating to that service as they may require. Seven practitioners have accordingly informed the committee that they have charged fees to insured persons in respect of (i) tonsillectomy and removal of adenoids; (ii) retinoscopy and prescribing of spectacles; (iii) refraction under mydriatic and ophthalmoscopic examination; (iv) estimation of error of refraction by retinoscopy, ophthalmoscopy, and subjectively, and prescription; (v) ultra-violet rays for neurasthenia and anaemia; (vi) refraction and ophthalmoscopic examination for myopic astigmatism; (vii) refraction and ophthalmoscopic examination for high myopia; (viii) mercury vapour, ultra-violet ray, and infra-red ray treatment for acute bronchitis; (ix) refraction for myopic astigmatism and anisometropia (retinoscopy and ophthalmoscopy); (x) refraction and ophthalmoscopic examination for hypermetropia and presbyopia; on the grounds that such services do not fall within the scope of medical benefit and that, owing to their special experience, the practitioners concerned were competent to undertake such services.

The opinion of the Local Medical Committee has been sought, and they have informed us that the services as described fall into the category of services involving the

application of special skill and experience of a degree or kind which general practitioners as a class cannot reasonably be expected to possess, and that they have satisfied themselves that the practitioners concerned possess the necessary skill and experience for the effective undertaking of such services.

With this opinion of the Local Medical Committee the Insurance Committee concurred on the recommendation of the Medical Benefit Subcommittee. It should be borne in mind that it is open to the Minister to refer to referees (two of whom must be doctors, the third being a barrister or solicitor in practice) any question upon which the Insurance Committee and the Panel Committee are in agreement, and that the regulations provide that, where the committees do not agree, the matter must be so referred. It should also be remembered that in every instance the decision is based on the facts of the particular case, and is not therefore necessarily of decisive authority in determining any other apparently similar case.

Where any medical service has actually been rendered to one of his insurance patients by an insurance practitioner it will be presumed that it is treatment falling within the scope of his insurance contract unless he proves otherwise; and the first step—if he wishes to establish a claim to a fee for the service as being of a specialist character—is that he should give notice to the Insurance Committee within two days after the date on which the treatment is given, the notice being on a form to be supplied by the committee for the purpose, with such particulars relating to the service rendered as it may require.

Authorized Appliances

Those who read carefully the reports of the meetings of the Insurance Acts Committee will have observed that at nearly every meeting there are requests from Panel Committees for additions to the schedule of appliances in the Medical Benefit Regulations, and that on most occasions the committee is unable to discover any good reason for endorsing the suggestions and passing them to the Ministry of Health. Insurance Committees, as well as Panel Committees, are sometimes apt to overlook the fact that the amount of money available in the Drug Fund is definitely limited, and that, if once the principle that appliances can only be authorized where their exclusion would constitute a hardship to a large number of insured persons is departed from it would be difficult to resist the inclusion in the schedule to the regulations of any and every appliance. In other words, it would be necessary to abandon the principle in the National Health Insurance Act that, whereas "proper and sufficient medicines" are given as part of medical benefit, only such appliances can be provided as are authorized by the regulations.

For convenience of reference the latest list of appliances (authorized by the Medical Benefit Amendment Regulations, 1933) is here set out:

Adhesive plaster, Spread, as described in the Drug Tariff for the time being in force.	Droppers, when required for the proper administration of any drug forming part of medical benefit.
Bandages:	Eye baths.
Calico.	Gauzes, surgical, medicated and unmedicated.
Crêpe.	Gauze and cotton-wool tissue.
Domette.	Hypodermic needles (for self-administration of insulin).
Elastic-web.	Hypodermic syringes (for self-administration of insulin).
Elastic adhesive.	Ice-bags:
Flannel.	Check sheeting.
India-rubber.	India-rubber.
Muslin.	Lints, surgical, medicated and unmedicated.
Open-weave.	Pessaries, ring.
Plaster-of-Paris.	Protectives:
Suspensory, cotton.	Gutta-percha tissue.
Triangular.	Jacquet.
Zinc paste.	Oiled cambric.
Brushes, when required for the proper administration of any drug forming part of medical benefit.	Oiled paper.
Catheters, urethral, and lubricant for use therewith.	Oiled silk.
Gum-elastic.	Sphagnum moss.
Soft rubber.	Spilints.
Cellulose tissue.	Tampons.
Cellulose wadding.	Tows:
Cotton-wools, absorbent:	Carbolized.
Boric.	Unmedicated.
Unmedicated.	

THE LANCASHIRE AND CHESHIRE BRANCH

A BRIEF HISTORICAL SKETCH (1837-49)

BY

J. S. MANSON, M.D.

PRESIDENT OF THE BRANCH

Science has a wider meaning than the discovery, accumulation, and classification of facts. It deals, or should deal, with the ideas, hypotheses, and theories which have either led to discoveries or which have issued from facts patent to all and accepted as incontrovertible. This statement means that a knowledge of science is incomplete without a knowledge of its history—how ideas originated and developed, and the circumstances and conditions antecedent to such origin and development. In medical science the establishment of the University, Faculties and the Royal Colleges was an important step in the organization of the profession for the purpose of giving that publicity to medical knowledge necessary for the adequate training and education of medical practitioners. After student days the Faculties and Colleges lost much of their influence because of their attachment to certain limited areas. Practitioners spread abroad and lost touch with their mentors of early years. In the first third of the nineteenth century the latent desire for co-operation in the exchange of ideas and for a wider diffusion of medical knowledge began to find expression among many medical practitioners, and as means of communication improved by the development of railways medical men formed groups throughout the country. The Provincial Medical and Surgical Association, afterwards the British Medical Association, was founded at Worcester, 1832, by Sir Charles Hastings, the East Anglian Branch in 1835, and the Lancashire and Cheshire Branch in 1837.

After the annual meeting of the Branch at Warrington, in June, 1933, Dr. Bowden of Warrington handed a number of newspaper cuttings and printed documents dealing with the establishment and early meetings of the Branch to Mr. McAdam, the librarian of the Warrington Library, for safe keeping. These were formerly the property of Dr. Charles White of this town, who died in 1912 after practising here for fifty years. It occurred to me that many would be interested in a brief sketch of the early history of the Branch based on records which I will present in chronological order. The presentation will be condensed, but many extracts will be given verbatim.

ABSTRACTS FROM THE RECORDS

A cutting from an unnamed newspaper gives a brief account of the inaugural meeting at the Legh Arms Hotel, Newton, on June 30th, 1837. Dr. Holme, senior physician of the Manchester Royal Infirmary, was elected chairman; forty others were present from Lancashire and Cheshire. Dr. Holme explained the object of the meeting, which was to set up an association of medical practitioners. It was agreed to name it the Newton Medical and Surgical Association. Dr. Jeffreys of Liverpool informed the meeting that Dr. Rutter of Liverpool regretted his inability to be present. He had, however, sent a number of copies of the address given by him at the opening of Liverpool Medical Institution. After the meeting the members dined. The toast of "The Queen" and other toasts were honoured. Admirable speeches were delivered by Drs. Holme, Jeffreys, Scott, Kendrick, and others. The meetings were intended to be held annually at Newton. Drs. John Sharp and G. W. Hardy of Warrington were appointed secretaries.

The second meeting was held on June 21st, 1838, at Legh Arms Hotel, Newton. Dr. Jeffreys succeeded Dr. Holme as president. Dr. Kendrick of Warrington and Dr. Black of Bolton were appointed vice-presidents. Fifty others were present. Dr. Jeffreys gave a presidential address, touching, among other matters, on the inadequate remuneration of rural practitioners under the regulations of the Poor Law Act. Dr. Jones of Chester read an admirable account of two cases illustrative of the pathology of the brain and nervous system.

LEGH ARMS HOTEL, NEWTON-LE-WILLOWS, LANCASHIRE, 1835.

Dr. Kendrick read an interesting and affecting memoir of Mr. Park, surgeon, of Liverpool. Dinner at 3 o'clock. Excellent speeches by Drs. Jeffreys, Jones, Lyon, Scott, Black, Twenlow, and Hardy, etc. Owing to the train leaving at 6.30 many had to depart to their great regret, as they were deprived of speeches by several eloquent individuals.

The third meeting was held on June 27th, 1839, at Warrington. Mr. James Ainsworth, president. Dr. Jones of Chester and Mr. John Moore of Bolton, vice-presidents. A circular was printed announcing that this meeting was to be held on June 20th at the Legh Arms, Newton. This early date was fixed owing to the near approach of the meeting of the parent Association at Liverpool. Owing to some hitch with the landlord of the Legh Arms Hotel this circular was not issued, and another was printed announcing that the third meeting would be held at Warrington on June 27th. "Members to assemble at the Music Hall, Bewsey Street, and then, at 3 o'clock, to adjourn to the Nag's Head Hotel, Sankey Street, for dinner. Twelve shillings each including wine and dessert." The circular also announced that—

"In consequence of the alteration in the time of the Grand Junction Railway trains starting on and after the 20th inst., that those in the morning leave their respective stations at a quarter past eight and half-past ten o'clock. From Birmingham at six o'clock. In the evening trains leave Warrington for Liverpool and Manchester at ten minutes to six, at sixteen minutes before eight, and twenty minutes past eight. For Birmingham at ten minutes to eight. In order to accommodate those members who may wish to proceed to Newton to meet trains from Liverpool and Manchester a carriage will be provided to convey them there free of expense."

This meeting was also advertised in the *Liverpool Mail*, the *Liverpool Mercury*, the *Manchester Guardian*, and the *Courier*. Forty members were present. At the business meeting in the Music Hall, Bewsey Street, Dr. Scott read an interesting memoir of Dr. Rutter of Liverpool. Dr. Buck read a paper on "Statistics with their Application to Medicine." Dr. Banner of Liverpool read a paper on "Injuries of the Head." Dr. Kendrick of Warrington gave a detailed account of a case of tuberculous disease in a female, illustrated with coloured drawings.

"Afterwards an excellent dinner was provided at the Nag's Head, which comprised all the best stores and art à la cuisine, and which along with the early and rare vegetables and fruits of the season, and the produce of a good cellar, drew from the company many encomiums on the attentive and generous landlord. The worthy President with his coadjutors, the vice-presidents, conducted the convivial part of the day's proceedings with great tact, grace, good humour, and order. Many loyal and professional toasts were given; which as they complimented several members on their talents, and the situations they held in the Association, or in the public institutions of the district, drew forth some very appropriate and eloquent speeches. The utmost harmony and good fellowship continued throughout the evening till the stern summons of the railway carriages broke up the feast of reason and flow of soul, leaving a strong impression on the few honoured visitors present that though doctors are proverbially said to differ, yet during the whole of this occasion they were as one and undivided."

There is a copy of the printed minutes of this meeting with report of the Council. One paragraph runs as follows: "As yet the Association may be said to be in a state of infancy, its operations are not fully matured, and although its resources are abundantly extensive, the means by which these may be rendered subservient to the extension of medical knowledge are not yet perfectly organized. Your Council therefore have rather to point out what may be done than refer to what has hitherto been effected." There were then ninety-two members, sixteen having joined during the past year. The finances of the Association showed a balance in hand of £2 17s 2½d., subscriptions of new members £4 10s., total £27 7s. 2½d. Expenses—printing, stationery, etc., £6 4s. 8d.; balance £1 2s. 6½d. The rules of the Branch are given in this document.

After the first meeting on June 30th, 1837, the Branch joined the Provincial Medical and Surgical Association on August 17th, 1837. Members were required to pay one guinea in advance to the Provincial Medical and Surgical Association, due on January 1st each year. There was also 5s. for admission to the local branch for its own use, and if necessary the Council could call for another 2s. 6d. Members who joined the Newton Association before August 17th, 1837, but who were not desirous of joining the Provincial Medical and Surgical Association could continue members of the local

branch with all its privileges except those of receiving the publications of the parent Association and enrolment in its list of members. The list of members contains names from the towns and districts within a radius of twenty miles from Liverpool and Manchester. One name I must mention—namely, Thomas Fawsitt of Oldham. He would be the father of Thomas Fawsitt of Oldham who was president of the Branch in 1925. No mention is made of practitioners from Southport, Wigan, Preston, Burnley, Blackburn, and districts north of Bolton, Rochdale, and St. Helens.

The fourth meeting was held at the Legh Arms Hotel, Newton. Dr. Samuel McCulloch of Liverpool, president, Mr. Wm. Goodlad of Manchester and Dr. Green of Newton vice-presidents. There were now ninety-eight members. This meeting is important as showing that the question of the status of the profession and its disabilities were occupying the minds of the members. The report of the Council states:

"When we regard the number of sources from whence diplomas and licences to practise are issued, the great diversity which exists in the preparatory education required from those who obtain them, or the total absence of everything like legal protection against fraudulent and destructive practices of ignorant and unprincipled pretenders, the present state of the medical profession in this country is most unsatisfactory."

Vaccination against small-pox was also a feature of interest. There were two Bills before Parliament. The report says:

"The Council are of opinion that one Bill is sufficient, also that any measure which sanctions the practice of inoculation (that is, with variolous matter) either directly or indirectly they conceive to be dangerous to the public health, and any law which consigns a medical practitioner to prison for an act which circumstances may require him to perform is too arbitrary and despotic for the enlightened age in which we live."

Dr. Kendrick of Warrington read a paper on vaccination at this meeting. He said that since the experiments of Mr. Ceeley there could be no doubt as to the identity of the two diseases—small-pox and cow-pox. He was a firm believer in the efficacy of vaccination, and laid down five rules for the control of small-pox: (1) Heavy fine on anyone inoculating with variolous matter or for willfully exposing an individual to the infection of small-pox. (2) Vaccination to be performed only by duly authorized practitioners, who should keep a register of vaccinations and issue certificates to the vaccinated. (3) These practitioners to be paid a fair remuneration by public authority. (4) No unauthorized person to be allowed to vaccinate. (5) That a certificate of vaccination be required from every person over 4 years of age receiving free education or parish relief." A set of forty-six questions was drawn up by Dr. Kendrick and issued to members on the subject of vaccination and small-pox. After the business meeting forty members sat down to an elegant dinner served with great profusion by the new landlady of the Legh Arms. On the removal of the cloth various loyal and constitutional toasts were given and drunk with enthusiasm, and the day being the anniversary of the Battle of Waterloo, the health of the Duke of Wellington as the hero of a hundred fights—not as a statesman—was not forgotten.

The sixth meeting was held at Newton, July 7th, 1842. President, Dr. James Kendrick of Warrington. The members continued to be interested in medical reform and legislation to improve the status of the profession.

The seventh meeting, held at Newton, June 29th, 1843. President, Mr. Wm. James Wilson, surgeon, of Manchester. There are two items of interest in the council's report: Dr. Samuel Malins of Liverpool, lecturer on midwifery and surgeon to the Ladies' Charity, died in the prime of life, leaving a widow and a numerous family almost destitute. A sum of £20 was given by the Benevolent Fund of the Provincial Medical and Surgical Association, and it was reported that the fund had only £40 in hand. It was also reported that the fund had not received the support it deserved from members in this district. Drs. Sharp and Hardy of Warrington, the first secretaries of the Branch, retired at this meeting, and were succeeded by Dr. R. W. Scott of Liverpool and Mr. M. James Hutton of Manchester. Mr. Dicken of Middleton gave an account of removing a bell-shaped button from the right bronchus of a boy $8\frac{1}{2}$ years old through an

opening in the trachea by a pair of forceps specially devised by himself; the boy recovered perfectly. The button had been lodged in the bronchus for thirteen days.

The tenth meeting was held at Newton, on June 25th, 1846. President, Dr. R. W. Scott of Liverpool. The Branch was now becoming subdivided, with local secretaries: Manchester, Mr. John Hutton; Liverpool, Mr. Benjamin Barrow; Bolton, Mr. J. M. Robinson; Warrington, Mr. John Sharp.

At the thirteenth meeting, in 1849, the president was Mr. Robert Thorpe of Manchester. The name of the Branch was changed from the "Newton Branch" to the "Lancashire and Cheshire Branch of the Provincial Medical and Surgical Association." This and other rules were sanctioned by the General Council at Worcester, July 14th, 1849; and here endeth the tale of the records.

[Dr. Manson showed other records and exhibits of historical interest, including a copy of the first number of the *Provincial Medical and Surgical Journal*, dated October 3rd, 1840. The editors were Drs. Green and Streeten, and it contained fifteen pages of medical matter and nine pages of advertisements.]

CONCLUSION

This brief and somewhat bald sketch of the early history of the Branch purposely omits many details that would be wearisome to relate. Anyone specially interested can read the documents for themselves. My main object is to proclaim their existence and to revive the names of some of the men who were public-spirited and enthusiastic enough to start the organization to which we are the heirs. They furthered the cause by the rational and well-approved methods of professional and scientific discussion and a good dinner. They dealt with subjects that still interest us and claim our attention—the status of the profession, medical education, unqualified practice, fees, vaccination, and medical benevolence. They served their day and generation, and did what they could to give the profession of medicine its proper place in the hierarchy of the sciences, and to develop its usefulness to suffering humanity.

British Medical Association

CURRENT NOTES

Annual Meeting, Melbourne, 1935

The Council of the Association, having accepted for the first time an invitation to hold a meeting in Australia, where 7,000 members are gathered, is most anxious that the meeting shall be attended by a large and representative body of members from this side, and with this end in view has taken steps to ensure a good attendance by combining with the journey to Australia a tour "round the world," to be undertaken under exceptionally favourable conditions, both as to itinerary and as to the entertainment which will be afforded en route, and perhaps more especially at those overseas Branches of the Association which will be visited. All particulars are available from the Financial Secretary and Business Manager of the Association (B.M.A. House, Tavistock Square, W.C.1); and all bookings must be made by members through his office. It will materially assist if those who contemplate going would notify him at the earliest possible moment of their intentions and of the number of relatives and friends who will accompany them. Upon the number travelling will depend, to some extent, the conveniences of travel, and certain arrangements can only be made provided a large enough number of members journey together. The Council has appointed, as travel agents for the tour, Messrs. Pickfords Travel Service, 105-106, High Holborn, London, W.C.1, who will work with the office of the Financial Secretary, and from whose branches at a later date the detailed information will be available.

Southern Division, Trinidad.

There has reached the Council of the Association the first annual report of the Southern Division of the Trinidad and Tobago Branch, formed by that Branch in March, 1933. In the nine months of its existence the Division has held no fewer than ten meetings, the proceedings at all of which have included discussion of both clinical and medico-political matters. On an average 61 per cent. of the membership of the Division attended the meetings, and 96 per cent. of the members attended at least one of the meetings. For a first year's activity this record is believed to be unique.

Medical Charities: Social Functions

The annual charities ball, organized by the Brighton Division for medical charities, was held recently. This function is now one of the most popular and successful of the winter social functions in Brighton, and on this occasion approximately 440 persons were present. The substantial sum of £65 was raised for medical charities. The arrangements for the ball were in the hands of Mrs. Beresford and Miss Parry, who acted as chairman and secretary respectively.

The members of the Portsmouth Division held their annual *souper dansant* at Southsea on January 12th. This, the eighth annual dance, is now acknowledged to be the most attractive social function of the season, and approximately 500 persons were present. A sum of £120 was raised for medical charities, bringing the total sum contributed by these dances to £740. The arrangements were as usual in the capable hands of Dr. A. Mearns Fraser and Dr. H. H. Warren.

Naval and Military Appointments

ROYAL NAVAL MEDICAL SERVICE

Surgeon Commander H. H. Babington to the *Drake*, for Royal Naval Hospital, Plymouth.

Surgeon Commander (retired) R. N. W. W. Biddulph to the *Cardiff*.

Surgeon Lieutenant Commanders R. B. McKiver to the *Devonshire*; T. C. H. Neil to the *Pembroke*, for Royal Naval Barracks, Chatham; A. G. L. Brown, D.S.C., to the *Drake*, for Royal Naval Barracks; J. A. Cusack and G. Kirker to the *Victory*, for Royal Naval Barracks; R. A. Graff to the *President*, for post-graduate course.

Surgeon Lieutenants G. D. J. Ball to the *Pembroke*, for Royal Naval Barracks; R. G. Dingwall to the *Victory*, for Royal Marine Infirmary; A. F. Davy to the *Sutton*; C. P. Collins to the *Victory*, for Royal Naval Barracks; A. Long transferred to permanent list, seniority June 2nd, 1930.

W. D. Gunn and D. W. Walker have entered as Surgeon Lieutenants for short service, and are appointed to the *Victory*, for Haslar Hospital.

ROYAL NAVAL VOLUNTEER RESERVE

R. T. Grant has entered as Probationary Surgeon Sublieutenant, and is attached to List 2 of the Tyne Division.

ROYAL ARMY MEDICAL CORPS

Lieutenants J. B. George, J. T. Robinson, and M. A. Rea to be Captains.

The appointment of Lieutenant J. P. Douglas is antedated to April 12th, 1932, under the provisions of Article 26, Royal Warrant, but not to carry pay or allowances prior to April 12th, 1933.

ROYAL AIR FORCE MEDICAL SERVICE

Air Commodore H. V. Wells, C.B.E., is placed on the retired list, and relinquishes his appointment as Honorary Physician to the King.

Flight Lieutenant E. Corner is transferred to the Reserve, Class D (ii).

The commission granted to Flying Officer (now Flight Lieutenant) G. A. M. Knight is antedated to April 27th, 1930.

INDIAN MEDICAL SERVICE

Major-General Sir John W. D. Megaw, K.C.I.E., and Colonel F. E. Wilson have retired from the Service.

Colonel A. H. Proctor, D.S.O., is appointed Inspector-General of Civil Hospitals, United Provinces, as from December 9th, 1933.

Lieut.-Col. H. C. Buckley is appointed Inspector-General of Civil Hospitals, Bihar and Orissa, as from December 16th, 1933.

The services of Lieut.-Colonel R. C. Clifford, M.C., D.S.O., placed permanently at the disposal of the Government of United Provinces, as from June 20th, 1930.

Major R. Hay, an Agency Surgeon, is posted as Civil Surgeon Quetta, as from November 22nd, 1933.

Captain T. A. Doran to be Major.

The services of Captain H. S. Waters are replaced temporarily the disposal of the Government of Bombay as from October 10 1933.

The services of Captain J. C. Drummond are replaced temporarily at the disposal of the Government of Bengal.

Lieutenant G. W. Miller to be Captain (provisional).

Lieutenant F. W. Whiteman is restored to the establishment October 18th, 1933, and his seniority is antedated to October 18 1932.

Lieutenants J. W. Bowden, R. D. MacRae, and W. Mackie confirmed in their rank.

Association Notices

SCHOLARSHIPS AND GRANTS IN AID OF
SCIENTIFIC RESEARCH

Scholarships

The Council of the British Medical Association is prepared to receive applications for Research Scholarships follows: an Ernest Hart Memorial Scholarship, of the value of £200 per annum, a Walter Dixon Scholarship of the value of £200 per annum, and three Research Scholarships, each of the value of £150 per annum. The Scholarships are given to candidates whom the Science Committee of the Association recommends as qualified to undertake research in any subject (including State medicine) relating to the causation, prevention, or treatment of disease. Each Scholarship is tenable for one year, commencing on October 1st, 1934. A Scholar may be reappointed for not more than two additional terms. A Scholar is not necessarily required to devote the whole of his or her time to the work of research, but may hold a junior appointment at a university, medical school, or hospital, provided the duties of such appointment do not interfere with his or her work as a Scholar.

Grants

The Council of the British Medical Association is also prepared to receive applications for Grants for the assistance of research into the causation, treatment, or prevention of disease. Preference will be given, other things being equal, to members of the medical profession and to applicants who propose as subjects of investigation problems directly related to practical medicine.

Conditions of Award: Applications

Applications for Scholarships and Grants must be made not later than Saturday, May 12th, 1934, on the prescribed form, a copy of which will be supplied on application to the Medical Secretary of the Association, B.M.A. House, Tavistock Square, W.C.1. Applicants are required to furnish the names of three referees who are competent to speak as to their capacity for the research contemplated.

BRANCH AND DIVISION MEETINGS TO BE HELD

ABERDEEN BRANCH: CITY OF ABERDEEN DIVISION.—Tuesday, February 13th. Dr. A. E. Kidd (Dundee): "In and Around some Thermal Resorts of France."

BIRMINGHAM BRANCH.—Thursday, February 15th. Dr. T. L. Hardy: "Functional Disorders of the Colon."

DUNDEE BRANCH.—At Surgery Classroom, University College, Small's Wynd, Dundee, Wednesday, February 14th, 8.30 p.m. Professor John Anderson: Epidiascopic demonstration in colour of surgical subjects.
